Advances in foam trimming equipment such as fully automated CNC processing lines allow for economical conversion of foam buns into very sophisticated contoured parts (Fig. 24). At the same time, trim losses are minimized by specific software [188].

Figure 24. Contoured parts, produced by different trimming technologies

Form milling is used for rounding edges on seat backs and armrests as well as on seat pads. Due to the large variety of milling tools, any shape is possible (Fig. 25).

Figure 25. Shaping of flexible foam by milling

Other post-treatment methods include reticulation, impregnation, compression, welding, cementing, laminating with textiles or films by flame lamination or adhesive bonding, quilting, and covering.

The trimmed-off foam is flaked in suitable mills. The flakes can be used as filling material or are bonded to form flake-composite blocks, referred to as rebonded foam. These composite blocks are then fabricated similarly to normal foam slab stocks (see Section Recycling/Recovery of Polyurethanes).

7.1.1.5. *Applications*

The variety of properties and the continuous development of new foam grades and further processing techniques have made slabstock indispensable for many applications.

For furniture, the use of polyether foams extends from complete foam upholstery to the simple seat cushion. Very comfortable cushioning is achieved by combining types with different properties (e.g., density, hardness, or elasticity).

Full PUR foam mattresses at present account for approximately one-third of all mattresses sold in Europe. The relative low weight (e.g., versus latex foam) and the freedom of design by combining various foam types (high resilient, conventional, viscoelastic) and grades (density, hardness) in conjunction with advanced cutting systems have turned these mattresses into high-tech applications. All required grades of hardness are available, from the child's to the intervertebral disk mattress. Even in steel-spring mattresses, a layer of slabstock foam is used as cushioning and lining material.

An important field of application for slabstock foam is the lamination of fabrics. Polyester foams are preferred to polyether foams due to their melting properties and their specific cell structure. The foams can be bonded on one or two sides with textile widths by adhesive or flame lamination and are widely used for automotive interior trim applications such as seat covers or headliners.

Other applications in automotive industry are sun visor fillings, which can be manufactured from semirigid polyester foams, and sound-absorption materials for passenger, engine, and trunk compartments. PUR foams are also used as sealing and filter materials in the ventilation system. All foams for automobiles must satisfy the fire test MVSS 302 (see Section Fire Performance of Polyurethanes). Depending on the density and the chemical nature of the PUR foam (HR or conventional foam) flame retardants must be added to the foam formulation to meet this requirement.

In the clothing industry the above-mentioned laminated fabrics are incorporated into jackets and coats. Other applications are paddings in ski and sports boots and underlinings in the purse-making industry.

Flexible PUR foam is particularly suitable as a packaging material for fragile goods. Because of the variety of cutting processes, extremely complicated shapes can be produced for the transportation of goods.

The main application in the household sector is sponges. They are produced from both polyether and polyester foam in very diverse colors and shapes. They can be fine- or coarse-pored and range from extremely flexible to almost rigid. The foam's hydrophilicity can be increased by using special additives. The range of uses in the household includes adhesive, sealing, and jointing tapes as well as undercarpet padding, doormats, and cleaning brushes. Special grades can be obtained by bonding with thermoplastic films by high-frequency welding.

The ability of flexible foams to absorb airborne noise efficiently is exploited for noise abatement. The low thermal conductivity of flexible block foams is used for the thermal insulation of heat accumulators and pipes. For use as filter material, e.g., in ventilation and air-conditioning systems or as dust filter in breathing masks, the flow resistance of the foam must be reduced by post-treatment. Depending on technical requirements, the foam can also be used as a filter for liquids. Since the foams do not absorb X rays, they are an ideal material for the comfortable support of parts of the body during X ray exposure.

7.1.2. *Molded Flexible Foam*

The foam molding process is used when it is impossible or uneconomic to produce a complex geometry by trimming slabstock foam, or when the incorporation of metal inserts (for fastening cushioning units or coverings) or even steel springs (for furniture applications) is desired. A distinction is made between hot-cure molded foam and cold-cure molded foam.

7.1.2.1. *Production*

To produce hot-cure foam, trifunctional polyethers with a low content of highly reactive primary OH groups in the molecular mass range of 3000–5000 g/mol are reacted with toluene diisocyanate (TDI) with ca. 80 % of the 2,4′ isomer, e.g., Desmodur T80. The blowing agent is carbon dioxide, which is formed by the water-isocyanate reaction. Polyether polysiloxanes are employed for stabilizing the foam and due to the lower reactivity of the polyols, tin dioctanoate or other tin compounds are used to catalyze the polyurethane reaction, amines are used to catalyze the blowing reaction, and rather high mold temperatures must be applied. The hardness of the foams can be adjusted by adding grafted polyols for increased load-bearing properties or by using special polyols or additives for softer grades. The resulting foam is open-celled and does not require crushing for cell opening.

Cold-cure foams are produced from trifunctional polyethers with enhanced reactivity (high proportion of primary OH groups) in the molecular mass range of 5000–6000 g/mol and grafted polyols. A variety of different isocyanates are used, usually with a functionality exceeding two (modified TDI types, blends of TDI and higher functional MDI; special MDI types). If pure TDI 80 is applied, polyethers with a functionality slightly higher than three are usually used (e.g., Hyperlite). No further blowing agents are used; the carbon dioxide formed from the reaction of water with isocyanate is the sole blowing agent. Due to the higher reactivity of the polyols no metal catalysts are required for curing, and the mold temperatures are relatively low (“cold” cure) compared to hot-cure foam. On demolding the cold-cure foam is closed-celled and must be mechanically crushed to avoid shrinkage and to achieve consistent physical properties.

7.1.2.2. *Molding Process*

The molding methods for hot- and cold-cure foam systems differ sharply from each other. This is mainly because external heat must be supplied to a hot-cure molded foam to cure the foam's surface fast enough.

Figure 26 shows the individual process steps of the hot-cure foam molding process. This production sequence has a cycle time of ca. 20–25 min, depending on the nature and size of the foam parts.

Figure 26. Plant for hot-cure moldings

a) Oven (160–250°C); b) Recirculating air/water bath; c) Cooling section; d) Working section; e) Inserts

The molds consist of black iron plate (wall thickness 1.5–2.0 mm), aluminum sheet (wall thickness 4–6 mm), or cast aluminum (wall thickness 6–10 mm). Since the foaming process for this foam type must proceed unpressurized, good mold venting is necessary. The arrangement of the vent holes is determined experimentally. In manufacturing the molds, a volume loss during the curing process of ca. 2 % must be taken into consideration. The precise value is specific for the formulation and must be determined experimentally. Release agents are mainly aqueous wax or soap dispersions. High- or low-pressure machines, operating batchwise, are used for metering the raw materials. The molds are usually heated by hot-air ovens. The heating capacity of the ovens for the full-cure process must be adapted to the mold material and the required cycle time. After removing the molded foam parts, the molds are cooled by water or cold air to the loading temperature.

The curing process can be shortened by rapid adjustment of the internal wall temperature of the mold to ca. 120 °C after the end of the rising time. In this case, the molds are heated directly with liquid heating media to conserve energy.

Cold-cure foam systems require much lower mold temperatures. To achieve the optimum quality of the foam skin, the molds are adjusted to the optimum temperature for the mold material and the release agent (between 40 and 65 °C). Cooling equipment is not required (Fig. 27). Depending on the combination of polyols, the isocyanate, the catalyst package, and the shape of the cavity, the foam can be demolded after 2–6 min.

Figure 27. Plant for cold-cure moldings

T = thermostatting units

In contrast to open-celled, hot-cure molded foam, the closed cells of cold-cure foam parts must be mechanically opened. This can be achieved by roller crushers with counter-rotating rollers, compressing the parts to a fraction of their original

height, or by fast alteration of the ambient pressure in a pressure chamber.

One hour after demolding, cold-cure molded foams have reached only 50–80 % of their final hardness. Therefore, cold-cure foam parts need to be handled with care in the first few hours after production. Depending on the chemistry and the climatic conditions, final properties are achieved after 5–12 h (for comparison: a hot-cure foam will reach its final hardness within the first 2 h after demolding).

The foam molds must be designed for an internal mold overpressure of 0.3–0.6 bar. When fabricating the master patterns for the mold replica, a loss in volume of the molded part of up to 2 % must be taken into account.

Larger plants (greater space requirement, more molds) are required for the production of hot-cure foam than for cold-cure foam, owing to both the heating/cooling cycle and the longer mold holdup times of ca. 12 min compared to 4–8 min for cold-cure foam. Under ideal conditions, hot-cure molded foam has the advantage of a lower molding mass compared to cold foams at the same compression-load deflection.

7.1.2.3. *Properties*

Hot-cure and cold-cure foams differ fundamentally in their mechanical properties. The lowest densities can be achieved with hot-cure foam. At the same density, a hot-cure foam will usually provide a higher hardness. However, due to higher venting losses, savings in material for a hot-molded piece of foam are significantly lower than expected based on the simple comparison of apparent densities. The compression load deflection curves of molded foams can be compared with that of free-rise flexible foams (Section Properties): the characteristics of hot-cure molded foam are similar to those of conventional slabstock foam; cold-cure molded foam can be compared with HR slabstock. The hysteresis curves show that cold-cure foam has a higher elasticity (narrower hysteresis loop) than molded parts from hot-cure foam. Table 7 gives a general overview of the properties of hot- and cold-cure foams.

Table 7. Average properties for seat grades of flexible molded foams

Property	Hot-cure foam	Cold-cure foam	
		TDI based	MDI based
	HC	HR-T	HR-M
Apparent density (EN-ISO 845), kg/m^3	28 – 40	35 – 50	45 – 65
CLD-Hardness at 40 % (EN-ISO 3386-1), kPa	3 – 7	2 – 8	4 – 12
Compression set 50 %, 70 °C, 22 h (EN-ISO 1856), %	2 – 4	4 – 8	4 – 8
Elongation (EN-ISO 1798), %	120 – 160	100 – 150	90 – 120
Tensile strength (EN-ISO 1798), kPa	80 – 140	130 – 200	100 – 160
Tear strength (ASTM D 3574-F), N/m	200 – 400	200 – 450	160 – 250
Humid ageing (OEM specific)	very good	good	good – very good
Hysteresis (Energy Dissipation)	high	low	medium

With a cold-cure foam cushion, greater comfort is experienced due to its higher elasticity. However, for an automobile seat this higher elasticity means a reduced damping of the vehicle's vibrations. Since the construction of the seat (full foam or combination of foam and springs) and the damping behavior of the vehicle structure must be matched, the question whether to use hot-cure or cold-cure molded foam must be decided for each individual case. A second and more basic difference between hot- and cold-cure foam is their fire behavior. Cold-cure foams down to a density of ca. 35 kg/m^3 usually meet the fire standards of the automobile industry, even without added flame retardants. For hot-molded foam, flame retardants must be used.

7.1.2.4. *Applications*

Flexible molded foams are principally used in all kinds of seat pads, seat cushions, backrests, bench seats, headrests, etc. in passenger cars (see Fig. 35), motorcycles, and commercial vehicles, aircraft, and railways. Another important area of application in the automotive industry is sound abatement. Flexible molded foam is used either on its own for absorption of airborne noise or as a composite in conjunction with a heavy layer (EPDM, EVA, or PUR elastomers filled with, e.g., barium sulfate) or as backfilling foam on the vehicle’s floor cover. These composites may act either as sound barriers or can be tailored to dampen structureborne noise. In addition, flexible molded foams are used in the furniture industry, e.g., for office chairs, armrests, and in specific combinations with steel springs, which are incorporated into the molded foam. Sealing lips for passenger car tail lamps and for filters can also be produced from molded foams.

7.2. Semirigid Foams

7.2.1. *Applications*

Semirigid foams are used primarily for improving inner safety and comfort in automobiles. Combined with an external layer of ABS/PVS or PUR skin and a metal or plastic carrier, they are used to produce instrument panels (dash boards), door

and pillar covers, armrests, and consoles. The foam has a density range of 80–180 kg/m^3 in the finished part. Key properties are long-term adhesion to skin and carrier, a uniform, fine cell structure, low emission, and high resistance to aging and heat.

Special grades (EA foams) are optimized for energy absorption. On impact, they dissipate the kinetic energy by deformation and thus protect the passengers in a crash (Fig. 28).

Figure 28. Dynamic force–deformation characteristics of a semi-rigid PUR foam

7.2.2. *Production*

Parts made of semirigid foam are produced mostly in a two-step process. First, the preformed skin (ABS/PVC by thermoforming or PUR by spraying) is positioned in the cavity of the mold. A plastic or metal carrier is fixed on the lid of the mold. In the second step, the mold is closed and the semirigid foam is injected. Alternately, the semirigid foam is spread in the open mold and the lid is closed before the foam expands.

The two PUR components are mixed by high-pressure machines. The molds are made from aluminum, often coated with epoxy resin. If the foam has contact to the surface of a mold, a wax-based release agent must be used. The demold times are between 1 and 6 min, depending on the size, thickness, and geometry of the parts and on the reactivity of the foam system.

7.2.3. *Properties*

Semirigid foams are mostly open-celled and have a higher compression load deflection and lower elasticity than flexible foams. Typical properties are:

Apparent density (ISO 845)	80–180 kg/m^3
Tensile strength (ISO 1798)	300–400 kPa
Elongation at break (ISO 1798)	30–60 %
Compression load deflection at 40 % compression (ISO 3386)	80–200 kPa
Compression set at 50 % compression (ISO 1856) 22h at 70 °C	< 10 %

The dynamic impact characteristics (Fig. 28) are important for the dampening and energy absorbing behavior.

7.3. Rigid Foams

Rigid foam is in most cases a closed-cell material that is used for thermal insulation. Besides providing thermal insulation the foam may also have to bear mechanical loads in some applications. Composite structures in which the self-adhesive effect is used to bond the foam to a substrate during the foaming process are often found in the field of rigid foam. This reinforcing sandwich-effect improves the mechanical properties significantly.

Rigid foam is used in many ways. The main applications for rigid foam are appliances (refrigerators, freezers), insulation boards (with and without facings), composite panels (mostly with metal facings), pipe insulation (as insulating shells or as composites), insulated containers, and in situ foam (spray foam).

7.3.1. *Raw Materials*

Rigid PURs require a highly cross-linked molecular structure. To achieve this, raw materials with high functionalities and low molecular weight are preferred on the polyol and on the isocyanate side. Therefore, short-chain polyether polyols and polymeric MDI are the materials of choice. Low molecular weight polyester polyols are also used.

Typical polyether polyols (see Section Polyether Polyols) are produced from a highly functional starter molecule (sucrose, sorbitol, glycerol, diethylene glycol, ethylenediamine, and others) or mixtures thereof by adding alkylene oxides, mainly propylene oxide but sometimes ethylene oxide. The resulting products are viscous liquids.

The *polyester polyols* (see Section Polyester Polyols) are typically based on aromatic acids like phthalic acid. (Di)ethylene glycol is mostly used as alcoholic component. Glycerol or other highly functional alcohol components may be used to increase the functionality. However, the use of starting materials with higher functionalities is limited because of the increasing viscosities of the resulting products.

The *polymeric* MDI types (see Section Aromatic Polyisocyanates) that are used have functionalities in the range of roughly 2.5 to 3.5, corresponding to viscosities of about 100 to 1000 mPa · s at 25 °C.

Blowing agents (see Section Catalysts and Additives) are not only used to create the foam. Since the blowing agent remains inside the closed cells it has a strong influence on the thermal conductivity of the resulting foam. The choice of the

blowing agent depends on the most important criteria in the respective application, such as the lowest possible thermal conductivity, processability, or relationship between cost and performance. In most cases, a combination of a physical blowing agent (a low-boiling liquid or a gas) and a chemical blowing agent (mostly carbon dioxide formed by the chemical reaction of water with isocyanate) is used. While, according to the Montreal Protocol, the use of chlorine-containing halogenated hydrocarbons is still allowed in certain areas of the world, the use of these products in Western Europe is banned. Here only fluorinated hydrocarbons such as tetrafluoroethane (R 134a), pentafluoropropane (R 245fa), and pentafluorobutane (R 365mfc) may be used. Hydrocarbons such as n-, iso-, and cyclopentane or mixtures with other hydrocarbons like propane or butane are widely used, despite their flammability. Methods for a safe handling of these products are industrially available and installed. All these blowing agents have very small coefficients of diffusion; they remain within the foam during its lifetime. Where no (metallic) facings are provided, the thermal conductivity increases very slowly because of air diffusing into the foam. Therefore, in some applications, e.g., the construction industry, increments are added to the measured values of the thermal conductivity to take this ageing process into account. In this way it is ensured that a sufficient level of insulation is installed.

Catalysts (see Section Catalysts and Additives), sometimes called activators, are used to control the foaming process. Products used as catalysts are tertiary amines, organometallic compounds, and alkali metal and quarternary ammonium salts of carboxylic acids. The products may be classified according to their performance-without really being able to draw sharp lines-as blowing, gel, and trimerization catalysts. A few examples taken from a wide range of products are given here: bis[2-(N,N-dimethylamino)ethyl]ether and *N*,*N*-bis(*N′*,*N′*-dimethylaminoethyl)methylamine as blowing catalysts; triethylenediamine (dissolved) and dibutyltin dilaurate as gel catalysts and potassium acetate (dissolved) and 1,3,5-tris(3-(dimethylamino)propyl)hexahydrotriazine as trimerization catalysts.

Foam stabilizers (see Section Catalysts and Additives), also called surfactants, are required to prevent the small bubbles in the liquid reaction mixture from coagulating. Fine-celled foams can be prepared by using these products. To produce foams with a fine cell structure, some air (or other inert gases) may be dispersed into the polyol component or into the reaction mixture for nucleation. A fine cell structure is important for a low thermal conductivity. Chemically, most of the products used in the industry are polyether-modified polysiloxanes. The structural variations possible by using different polyethers and different polysiloxanes lead to the great number of products available on the market, optimized for various purposes. Some of these purposes are: flowability (describes the expansion of the foam into narrow cavities), adhesion to facings (the force required to remove the facing), fine cell structure (small cells of similar size), and flammability (resistivity to flames or high temperatures).

Flame retardants (see Section Catalysts and Additives) are used to make the foams less flammable. The methods for testing flammability are manifold. However, official requirements regarding flammability are in place for some applications, e.g., in the construction industry. Since PUR foams are based on organic molecules, it is only possible to achieve certain flammability classifications within the group of flammable materials. Flame retardants used in the field are usually substances based on halogens and/or phosphorus. Some products have OH groups, so they can react with isocyanate and are incorporated into the macromolecule; others are nonreactive. Examples of reactive flame retardants are polyethers made from dibromobutenediol and epichlorohydrin or brominated aromatic polyester polyols. Examples of nonreactive flame-retardants are tris(2-chloroisopropyl)phosphate, diphenyl cresyl phosphate, and dimethyl propyl phosphonate. Apart from red phosphorus, which is used in the production of rigid slabstock foam by low-pressure mixing, solid flame retardants have hardly been used in the field of rigid foams. A technique has been developed for processing solid flame retardants continuously on high-pressure machines [189].

7.3.2. *Processing*

Mixtures of the raw materials mentioned above are processed to produce rigid foams. The foaming process is described and monitored by periods of time taken from the start of mixing:

The *cream time* is the time until the reaction mixture starts to expand. At this point in time, the exothermic reaction has heated the reaction mixture to a temperature at which the blowing agent is starting to evaporate. The gas formed remains in the reaction mixture and forms small bubbles that grow with increasing temperature and further formation of gas.

When the cross-linking of the polymer has progressed to the point where the liquid reaction mixture starts turning into a solid the *gel time* can be observed. This is mostly done by prodding the foam with a small stick. When fibers of polymer are pulled from the rising foam the gel time has been reached.

After that the foam continues to rise to its final height (*rise time*).

The *tack-free time* is the time required for the surface of the foam to lose its tackiness. The tack-free time may occur before or after the rise time.

The time required to cool down the foam depends on its thickness. For slabs 1 m in height it takes more than 24 h until ambient temperature is reached in the core. In all processes the foam applies pressure on the compartment in which it is contained. To keep the parts produced within their specified dimensions, the molds must withstand this pressure until the foam has reached a minimum strength and the part can be demolded (demold time). In continuous processes, the line speed needs to be adjusted to keep the foam in the machine for the time required to cure sufficiently. For thicker parts the demold times are longer than for thinner parts, and therefore the line speeds in a continuous production are slower for thicker parts.

Preblending some of the components-usually into the polyol side-for easier operation can be done at different levels. It can be performed by the raw material supplier or by the processor. This depends mostly on the variability required for the respective process (e.g., adjusting reactivity in continuous processes).

A discontinuous process (sometimes called a one-shot process) is used in cases where particular cavities are to be filled,

such as in the production of refrigerators, freezers, insulated containers, and certain sandwich panels. Figure 29 shows the principle of filling refrigerator cabinets.

Figure 29. Principle of filling refrigerator cabinets

A) Door opening on top; B) Door opening on bottom

a) Pour-in opening; b) Ventilation openings

Figure 30 shows the discontinuous production of sandwich panels in a multistage press using the mixing head pull technique.

Figure 30. Production line for the discontinuous production of PUR composite elements

a) Plates of the press; b) Carrier on rolls for the hoses leading to the mixing head; c) Lifting device; d) Foam machine; e) Driving elements for horizontal movement; f) Cable holder; g) Device for closing the press; h) Closing cap for each unit; i) Mixing head with hoses; j) Opening device; k) Metal facers

In most of these applications only one type of reaction mixture is used for the whole production range. Here all the necessary components are preblended into the polyol so that only two components, i.e, this polyol formulation and the isocyanate component, must be provided. The components are tempered and metered to the mixing head by high-pressure pumps. The mixing itself is performed by using the high-pressure impingement mixing technique. The amount of reaction mixture necessary to fill the cavity is determined by the volume of the cavity and the density of the foam. The duration of the dosage is then given by the output of the pumps. This shot time must be shorter than the cream time to avoid pumping liquid reaction mixture into an already expanding foam. In so doing, the foam would be partially destroyed with negative effects on all of its properties.

In the continuous production of composite panels and insulation boards on double conveyor belts, the high-pressure impingement mixing technique is also used in most cases. The principle of this process is shown in Figure 31. Here the low weight of the mixing head and the hoses leading to it enable the oscillating of the mixing head across the moving bottom facing for an even distribution of the reaction mixture.

Figure 31. Principle of the continuous production of insulation board

A) With flexible facings; B) With profiled metal facings

a) Unwinding device; b) Lay-down with mixing head; c) Means for folding paper; d) Foaming reaction mixture; e) Compression; f) Cooling area; g) Longitudinal cutting; h) Transverse cutting; i) Coil unwinding; j) Corrugation rolls; k) Heating elements; l) Gate with moving high-pressure impingement mixing head

In the special case of the production of insulation boards on high-speed laminators at line speeds of up to 60 m/min, the high-pressure impingement mixing technique is used in most cases, but without oscillating the mixing head. The oscillation frequencies to ensure an even distribution of the reaction mixture on the bottom facing would be too high.

Here even distribution is achieved by passing the reaction mixture through a narrow gap between the top and the bottom facing (calibration technique). By this technique the small voids near the top facing that occur with the oscillating mixing head technique are eliminated. In all these applications it is necessary to adjust the reactivity of the reaction mixture according to the thickness of the board or panel. Also the amount of blowing agent must be adjusted. This means that the degree of preblending is lower than in a discontinuous process. Catalyst, blowing agent, and possibly other additives are metered separately into the polyol stream. Thus, only two components are finally led to the mixing head, keeping the moving weight low for the oscillation.

In the continuous production of rigid slabstock foam low-pressure mixing is used due to the high output. Here the components are metered into a mixing chamber and mixed by a mechanical stirrer. Separate metering of the components into the mixing head can be used. Preparing a polyol component containing all necessary components is also possible and allows for a certain quality control prior to foaming.

7.3.3. *Properties*

The most important property of rigid PUR foams is its low thermal conductivity, which is the lowest among the different insulation materials available by a significant amount. This allows for a smaller thickness of the insulating layer to achieve the same insulation value. The thermal conductivity of closed-cell PUR foams in the density range 25–60 kg/m^3 depends not so much on the apparent density (usually the thermal conductivity increases slightly with increasing density) but is dominated by the thermal conductivity of the blowing gas. The thermal conductivity can initially be near 0.020 W m^{-1} K^{-1}, and after ageing (cell gas diffusion) typically is in the range of 0.025–0.030 W m^{-1} K^{-1}.

The adhesion to substrates is important for composite constructions. The force needed to remove the foam from the substrate is the criterion used to judge adhesion.

Mechanical properties like compressive strength, tear strength, and shear strength are also important in load-bearing applications. Their values strongly depend on the density and the cell structure (Fig. 32).

Figure 32. Relationship between typical properties and apparent density of rigid PUR foam (values at room temperature)

a) Modulus of elasticity; b) Tensile strength; c) Compression strength

Dimensional stability must be given under the conditions of use of the respective application. Dimensional stability is tested at low temperatures (e.g., for freezers) and at high temperatures (e.g., for hot water tanks).

Flammability is a very important property of the foam or the composite or both, depending on the test that needs to be passed. Various test methods are in place, most of them in the construction and transportation industries. For example, a harmonized test for the construction industry has been introduced in the EU. The new test procedure comprises a test on the foam (small burner) and the single burning item (SBI) test on the final product under end-use conditions. Other test procedures, e.g., those set up by insurance companies, are also in place.

For the different applications the importance of the various properties is prioritized differently.

For appliances (commercial and domestic refrigerators, freezers, hot water tanks), a low thermal conductivity is of top priority. In these applications a maximum useable space is desired at minimum or given outer dimensions. For this reason, the thickness of the insulation is limited, and only with a foam that offers low thermal conductivity can the energy consumption be minimized. Dimensional stability at low and high temperatures is the other important property here. In the low temperature applications the foam also fulfils a structural task, it forms a type of sandwich structure with the inliner and the outer facing.

Preinsulated pipes are mostly used for district heating. Here the thermal conductivity and the lifetime expectancy are the important properties. Accelerated ageing tests at elevated temperatures are performed to ensure a lifetime of, for example, at least 30 years according to EN 253.

Insulation boards, predominantly those with facings (aluminum foil, mineral fleece, papers) produced on double conveyor belts, also require low thermal conductivity and dimensional stability. On larger insulated areas, e.g., flat roofs, shrinkage would lead to areas without insulation due to gaps between the boards, while swelling might make the boards lift up and break the protective cover. For decorative boards also the appearance is important. Wrinkled facings, mostly aluminum foil, or sink marks due to voids under the facing are unacceptable here. Since most of the products are used in construction, flammability is also an important property.

Composite panels, mostly produced continuously on double conveyor belts with profiled steel sheets as facings, are mainly used in the construction of walls and roofs of large buildings like warehouses or factory buildings. The prefabricated self-supporting panels are attached to a bearing frame construction, so that the complete wall or roof can be put together very fast. The most important properties here are adhesion of the facings, dimensional stability, flammability, and thermal conductivity. The appearance is also important, especially for panels in facades. The thickness of the panels depends on the use of the building. For cold storage houses, where goods are stored at -40 °C, panels up to 24 cm thick are used. The thickness of panels for factories (from about 20 to 100 mm) depends mostly on the local climate. Discontinuously produced panels may have locks for connecting panels with one another that are incorporated into the foam during the foaming process. These panels can be used without bearing constructions, e.g., for walk-in-coolers. Another application is the use of panels in roll-up doors; large ones for truck entrances in industrial buildings, and small ones for private garages.

Slabstock foam is made for applications in very different fields. A few examples are given here: low-temperature insulation (liquid gas tanks, also in ships); refrigerated containments for lorries, where the foam is covered with glass reinforced plastic; insulation for parts that are difficult to mold such as valves and flanges (here the foam is mechanically shaped); wedge-shaped boards to give flat roofs a slope; and others. Different properties are required in these different applications, so rigid slabstock foam is a specialty field. Foams with a range of densities from about 30 to over 200 kg/m^3, different flammability classifications, foams with glass fiber reinforcements, and other variations are found here.

7.3.4. *Special Types*

Foam from pressurized cans, mainly one-component-foam, is used for mounting and fixing applications such as windows and doorframes. Here all the raw materials, including blowing agent and isocyanate, are blended in the can to form a prepolymer with residual NCO groups. The propellant, that is, liquid under pressure, acts first as thinner for the prepolymer. When expelled the propellant acts as blowing agent to produce the foam. The foam itself is usually an open-cell product.

A few special types of open-cell foam exist, such as thermoformable rigid foam that is used in passenger car headliners, foam for flower-arranging purposes, and packaging foam. Recently some attempts have been taken to evacuate open cell foam to reduce the thermal conductivity even further. One problem here is to find suitable facings that ensure that the vacuum is maintained during the lifetime of the product.

In certain cases the foam must be applied in situ. Two methods are predominant: spraying and layer-by-layer application. Spray foam is mostly used for the industrial insulation of storage tanks or in the insulation of buildings. While spray foam on walls is only for insulation, foam on roofs is also applied for sealing purposes. Two-component systems are used here. The components are fed through heated hoses to the mixing head, which is designed like a spray gun. The reactivity of these systems is so high that the foam cures within a few seconds. In layer-by-layer application the reaction mixture is

poured between two substrates, e.g., the outside of a tank and the casing. This method is used where the application of the foam in a factory is not possible, e.g., because of the size of the tank. Here also two-component systems are used. In both cases special attention must be paid to temperature and humidity conditions. Foams should not be applied on cold or moist surfaces. Otherwise, problems with bonding the foam to the substrate may result.

Polyisocyanurate (PIR) foams [190-195], more precisely to be understood as polyisocyanurate-modified PUR foams, are products in which isocyanurate structures are incorporated into the macromolecule. These structures are formed due to the reaction of excess isocyanate with itself. Special (trimerization) catalysts are required. Three NCO groups form the cyclic isocyanurate structure, which shows a higher decomposition temperature than PUR groups. Therefore, these foams are used where flammability or heat resistance is an issue. However, this highly cross-linked structure increases the brittleness of the foams. The overall cross-linking density is controlled by the use of low-functionality polyols. In the continuous production of insulation boards on double conveyor belts, which is the major application for this type of foam, the PIR structure is usually combined with (aromatic) polyester polyols. The higher decomposition temperatures of esters compared to ethers also leads to an additional positive effect on the flammability of the foam. In the manufacturing of these foams, special attention must be paid to the temperature of the laminator because the trimerization only takes place at temperatures above 60 °C. Apart from the reduction of brittleness the polyols have the task of heating the reaction mixture by their exothermic reaction with isocyanate. When the required temperature is reached, the trimerization starts, which can often be observed as a second phase in the expansion of the foam.

7.4. Integral Skin Foams and RIM Materials [196-198]

Integral skin or self-skinning foams are products with a cellular core and a cell-free surface that are formed in a mold in a single operation (Fig. 33). Parts made by the reaction injection molding (RIM) process are microcellular materials with a high surface quality that are mostly painted.

Figure 33. Principle of density distribution for integral foam boards of 10 mm thickness and various apparent densities:

A) 0.2 g/cm^3; B) 0.6 g/cm^3; C) 1.1 g/cm^3

7.4.1. *Applications*

Flexible self-skinning foams are used mainly in the automotive, furniture, and footwear industries. Typical automotive applications are steering wheels and gearshift knobs, but also armrests and headrests (Fig. 34). In the footwear industry, integral skin foams are used for soles of sport, leisure, and safety shoes.

Figure 34. Use of PURs in the passenger car

A) Rigid integral foam; B) Rigid integral foam, glass-mat reinforced; C) Hot-moldable rigid foam; D) Semi-flexible integral foam; E) Semi-flexible integral foam, glass-fiber reinforced; F) Semi-flexible filling foam; G) Semi-flexible filling foam, impact-energy-absorbing ; H) Flexible molded foam; I) rigid foam; J) Hot-curing PUR elastomer; K) PUR rubber

RIM materials are used for exterior auto parts like fenders (Fig. 35A), panels, side protection and window encapsulation, but also for other exterior parts in agricultural machines or recreational vehicles like snowmobiles (Fig. 35B).

Figure 35. Use of integral skin foams and RIM materials

A) Fender of the VW Touareg; B) Snowmobile

Rigid integral skin foams or RIM materials can be used in many different applications, mainly for structural parts. They can favorably compete with wood, thermoplastics, thermosets, and metals. They are used for furniture, skis, pump housings, window frames, decorative applications, and housings, just to name a few characteristic applications.

7.4.2. *Production*

Integral skin foams are mostly manufactured in metallic (aluminum) or epoxy molds. Skin formation is controlled by addition of a low-boiling solvent in amounts of about 2–10 wt %, relative to the polyol mixture. After the banning of CFCs and HCFCs, currently HFCs (hydrofluorocarbons) or alkanes are used. When using alkanes, special precautions must be taken because of their flammability.

Thermodynamic equilibrium between the liquid and gaseous phases of the blowing agent in the reaction mixture is crucial for the formation of the closed surface. The mold temperature is kept between 40 and 60 °C, and the reaction mixture in the vicinity of the mold surface has a lower temperature than the core (up to 140 °C). In the core the blowing agent vaporizes, while near the edge it condenses, with formation of the solid surface.

The quality of the surface depends very much on the quality of the mold, but precise control of the processing pressures and temperatures is also required.

In special cases formation of an integral skin is possible without the addition of physical blowing agents. For this, temperature-controlled carbon dioxide formation from the NCO/H_2O reaction must be achieved.

High-pressure metering and mixing units are necessary for manufacturing of RIM parts. The processing of these materials, which are mostly of high reactivity, also requires closed, metallic molds and a clamping unit. To obtain void-free parts without porosity the reaction mixture must enter the mold cavity through a gate designed to ensure laminar flow. Also, correct venting of the mold at the highest points and nucleation of the reaction mixture by air or nitrogen are important for good quality.

After demolding, the parts must be trimmed, and gate and flash must be removed. The surface is prepared for painting by removal of the release agent by washing or sanding.

7.4.3. *Properties*

Depending on the field of use, soft-elastic moldings have densities of 100–300 kg/m^3, flexible molded articles 400–600 kg/m^3, and the relatively hard, microcellular elastomers 900–1100 kg/m^3.

Technical data for a typical soft integral skin foam of low density:

Density (ISO 845)	400 kg/m^3
Shore A hardness (DIN 53505)	35
Tensile strength (DIN 53504)	0.8 MPa
Elongation at break (DIN 53504)	85 %
Tear resistance (ISO 34)	1.4 kN/m
Compression set (25 %/70 h, RT; ISO 1856)	2.5 %

Mechanical properties of a flexible molding of medium density used in the footwear industry (e.g., polyester system):

Density (ISO 845)	500–600 kg/m^3
Shore A hardness (DIN 53505)	ca. 50
Tensile strength (ISO 1798)	6–8 MPa
Elongation at break (ISO 1798)	450–550 %
Tear propagation strength (ISO 34)	10–15 kN/m
Abrasion loss (DIN 53516)	50–100 mg

Mechanical properties of a microcellular elastomer molding of high density (e.g., automotive body parts):

Density (ISO 845)	1100 ± 50 kg/m^3
Shore D hardness (DIN 53505)	64 ± 3
Tensile strength (DIN 53504)	35 ± 3 MPa
Elongation at break (DIN 53504)	300 ± 30 %
Tear propagation strength with cut (ISO 34)	80 ± 10 kN/m
Modulus of elasticity according to Roelig	
at–30 °C	1400 ± 100 MPa
at + 20 °C	600 ± 50 MPa
at + 65 °C	360 ± 30 MPa

The technical data of rigid integral skin foams depend very much on the density, which can be anywhere between 150 and 1100 kg/m^3. Typical properties of a low-density rigid integral skin foam, as used for imitation wood follow:

Density (ISO 845)	400 kg/m^3
Shore D hardness (DIN 53505)	58
Flexural strength (ISO 178)	20 MPa
Flexural modulus of elasticity (ISO 178)	520 MPa
Impact strength (ISO 6603)	10 KJ/m^2
Heat deflection temperature (ISO 75)	90 °C

High-density rigid RIM materials, which are typically used at wall thickness between 3 and 5 mm, have the following characteristics:

Density (ISO 1183)	1100 kg/m^3

Shore D hardness (DIN 53505)	76
Flexural strength (ISO 178)	25–45 MPa
Flexural modulus of elasticity (ISO 178)	2000 MPa
Tensile strength (ISO 527)	53 MPa
Elongation at break (ISO 527)	14 %
Impact strength (ISO 179)	45 KJ/m^2
Heat deflection temperature (ISO 75)	115 °C

When flame retardancy tests are also considered, RIM materials are capable of passing burning tests such as UL 94 V-0 (Underwriters' Laboratories) or B2 (DIN 4102) by the addition of flame retardants.

Both flexible and rigid RIM materials can be reinforced with short or long glass or mineral fibers and also glass mats or mats made of natural fibers. These composite materials show considerably higher stiffness and especially impact strength.

8. Noncellular Polyurethanes

Geza Avar and Hans-Georg Wussow

Although the term "noncellular" is unambiguous, the terminology of the products treated in this chapter requires explanation. "Cellular Vulkollan," well known from the early days of PURs, already breached the borderline of precise definition. In practice, this material was not considered a "foam," although it can be undoubtedly classified as a foam from a strictly physical viewpoint because of its cellular structure, however small the few cells may be. The RIM technology has made the definitions even less distinct due to the terminology of "microcellular elastomers" on the one hand and "solid integral parts" on the other. In this chapter the problem of definition is solved as follows: All products which are based on a formulation that usually leads to a foam are classified as "foams," even if cell-free solid materials can be obtained by raising the apparent density (less blowing agent). Similarly, products which are based on formulations that usually result in noncellular materials are classified as noncellular PUR, even though they may be cellular, and these materials are treated in this chapter.

There are two different processing technologies for manufacturing these noncellular PURs. Liquid, low molecular mass raw material systems are converted to high molecular mass products by the reaction of the polyol and polyisocyanate components by cold or hot curing. Linear, high-molecular-mass raw material systems are either thermoplastically processable pellets or urethane rubber are processed by vulcanization technology.

8.1. Cast Elastomers

Cast elastomers are mostly solid, noncellular materials, produced in a low-pressure casting process from ester or ether prepolymers of MDI, TDI, and NDI (see Section Aromatic Polyisocyanates) and a cross-linker such as butanediol. If water-containing cross-linkers are used, cellular elastomers can also be obtained.

8.1.1. *Applications*

The highest quality elastomers are those derived from NDI [Tradenames: Vulkollan (Bayer MaterialScience), Cellasto (Elastogran)]. They are used where materials must meet extremely high requirements regarding durability and mechanical properties. Examples are high-load rolls and wheels for forklift trucks and machines, hydraulic seals, membranes, valve seats and balls, scrapers, and sieves. Cellular NDI-based elastomers are widely used in the automotive industry for bouncers and spring supports (Figs. 34 and 36).

Figure 36. Use of cellular Vulkollan as supplementary spring in the passenger car

Hot-curing elastomers based on MDI or TDI are used, e.g., for bottle stars in automatic filling machines, cutting wheels for fiber production, roll covers for the paper and printing industry, and wheels for in-line skates and skateboards.

Cold-curing PUR elastomers are used as binders for the surface of playgrounds and sport tracks. These surfaces are very durable, require little maintenance, can be used under all weather conditions, and reduce the risk of injuries. Other applications are seals for stoneware pipes, polishing disks, protective edges, and permanent fenders for boats. Cold-cure elastomers can also be sprayed on concrete or metal for corrosion protection and are used for the surfacing of bridges, parking decks, and terraces and for lining of wagons and trucks.

8.1.2. *Production.*

The raw materials used are low molecular mass glycols or amines, polyester or polyether polyols, and (modified) MDI-, TDI-, or NDI-type isocyanates.

The elastomers can be manufactured in a two-step or a one-step procedure. Figure 37 shows a typical line for the production of high-quality elastomers, as is used for NDI-based high-performance materials. The system passes through several stages: dehydration of the polyester (a), production of prepolymer from polyester and diisocyanate (b), degassing of the feed component (c), admixing of cross-linking agent (d), atmospheric-pressure casting in open molds (e, f), and fully curing the molding at 100–300 °C for several hours (g). This processing technique even allows the production of voluminous and thick-walled parts in relatively simple, inexpensive molds with low energy consumption. Depending on the system to be cast, steel, aluminum, and in special cases plastics or wood can be used as the mold material.

Figure 37. Flow chart for production of high-quality elastomer (e.g., Vulkollan/Baytec)

a) Dehydrogenation of the polyester; b) Prepolymer production; c) Cross-linker; d) Casting machine; e) Mold frame; f) Heating oven (thermal posttreatment)

For MDI and TDI stable prepolymers are commercially available, so that a one-step process can be used. The reactivity of the raw materials varies widely. Casting times between 2 and 60 min can be realized.

Cold-casting systems are usually processed with a casting machine. For some formulations that have a sufficiently long pot life, the starting components can also be hand mixed and cast. In this case the charge volumes are limited to a few liters. The reaction mixtures cure, without an external heat supply, within widely differing cure times, from less than 10 min to a maximum of 24 h. The castings reach their final strength after ca. 7 d storage at room temperature.

8.1.3. *Properties*

NDI-based elastomers have a temperature range for continuous use between –30 and +80 °C. At temperatures below 0 °C the material becomes increasingly hard and inelastic, though there is no danger of fracture. Embrittlement occurs only at very low temperatures (below –30 °C).

NDI elastomer (Vulkollan) is resistant to mineral oils, grease, gasoline, and most organic solvents. Gasoline and some solvents cause some swelling, but this does not impair its mechanical properties if the solvents are able to re-evaporate. Concentrated acids, alkalis, and other hydrolyzing media attack NDI elastomers. By incorporating additives or using special polyesters the hydrolytic stability can be increased so that the service life of the elastomers becomes adequate for a variety of uses even under extreme conditions. Mechanical properties of NDI elastomers are listed in Table 8.

Table 8. Mechanical properties of a hot-casting system (e.g., Vulkollan)*

Property	Vulkollan type			
	18/40	18	30	50
Shore hardness A/D (DIN 53505)	68/20	83/31	92/36	96/58
Density (ISO 1183), kg/m^3	1.25	1.25	1.26	1.26
Abrasion loss** (DIN 53516), mm^3	45 – 50	45 – 50	40 – 50	43 – 48
Tear propagation strength according to Graves (ISO 34), kN/m	20 – 30	40 – 55	67 – 85	85 – 96
Impact resilience (DIN 53512), %	48 – 55	45 – 50	45 – 50	45 – 50
Tensile strength (DIN 53504), MPa	42 – 49	50 – 60	37 – 45	40 – 43
Elongation at break (DIN 53504), %	600 – 700	630 – 750	550 – 650	330 – 370

*The properties listed here can only be regarded as approximate. For Vulkollan articles on the market, the quality characteristics specified by the manufacturer are applicable.
**Relative to abrasion-resistant grade of natural rubber (= 100).

Cellular NDI elastomers can be produced with densities of 300–700 kg/m^3 and are characterized by their high capability of absorbing energy on impact. The material can be compressed by up to 80 % of the original volume without damage. Damping units with various compression deformation characteristics can be manufactured from cellular Vulkollan by varying its apparent density, preferably in the range 300–600 kg/m^3.

Hot-casting systems with a base other than NDI are produced with Shore hardness grades from ca. 55A to 65D. The other mechanical properties and the chemical stability are basically comparable with those of NDI elastomers without reaching the same levels, especially in dynamic stability. They do not, however, reach the high values of Vulkollan in all points, as is also clear from the lower dynamic stability under load. MDI and TDI elastomers cannot replace Vulkollan but are used as supplementary products, primarily in fields where the high quality of Vulkollan is not absolutely necessary, where a system with long casting time is advantageous for producing large-volume and thick-walled moldings, and where short demolding times are desirable for producing large series.

Cold-curing products have a good elasticity, high flexibility, and a variable Shore hardness in the range of ca. 20A to 65D. They are highly resistant to aging and microorganisms and are not attacked by dilute acids and alkalis, mineral oils, soaps, or detergents. Organic solvents cause various degrees of swelling.

8.2. Thermoplastic Polyurethane Elastomers (TPU)

See also ⟶ Rubber, 3. Synthetic – Thermoplastic Polyurethanes, ⟶ Thermoplastic Elastomers – Thermoplastic Polyurethane Elastomers

Production. Diisocyanate (usually MDI), polyols (polyester and polyether polyols), chain extenders (butanediol), and the necessary auxiliaries are reacted in continuous plants via mixing heads or in reaction extruders. After solidifying, the product is processed further to pellets. The TPU can be processed further by, e.g., injection molding, extrusion, calendering, or blow molding to give finished or semi-finished products.

Properties. The principle of "tailor-made plastics" applies to the properties of thermoplastic PURs, as to all PURs. A very wide range of properties is available by careful choice of the starting materials. This is shown in Figures 38 and 39 as well as Table 9 for three selected examples.

Figure 38. Shear modulus for various TPUs (e.g., Desmopan)

a) Type 385; b) Type 790; c) Type 460

Figure 39. Mechanical loss factor for various TPUs (e.g., Desmopan)

a) Type 385; b) Type 790; c) Type 460

Table 9. Mechanical properties of different types of TPU (e.g., Desmopan)

Property	Desmopan system		
	385	460	790
Shore hardness A/D (ISO 868)	86/33	97/59	92/42
Density (ISO 1183), kg/m^3	1200	1210	1210
Tensile strength (ISO 527-1/-3), MPa	40	35	55
Elongation at break (ISO 527-1/-3), %	450	350	450
Tear propagation resistance (ISO 34-1), kN/m	80	120	85
Impact resilience (ISO 4662), %	42	35	32
Abrasion loss (ISO 4669), mm^3	30	40	30

Uses. The TPUs are valued as high-grade polymeric materials in many industrial branches for a great variety of constructional parts. Table 10 shows examples of their use in relation to their Shore hardness. Glass-fiber reinforced types are used for bodywork units.

Table 10. Typical applications for different grades of TPU

Hardness range		Uses
Shore A	Shore D	
75 – 90	< 35	membranes, seals, damping units, sieve units, hoses, cable sheatings
90 – 95	35 – 45	animal identification markings, roll coverings, toothed belts, sport shoe soles
> 95	45 – 55	seals, flanges, rolls, pneumatic hoses
	55 – 70	bearings, bushes, connectors, ball sockets, seals, coupling units, ski bootlegs, heel pieces

[Top of Page]

9. Polyurethane Coatings [199-201]

Karl-Ludwig Noble

See also ⟶ Paints and Coatings – Polyurethane Coatings

PUR coatings offer a large variety of outstanding properties, which make them suitable for many high-performance applications. PUR coatings have polymeric structures with urethane, urea, biuret, or allophanate coupling groups. They are generated either from reactive systems by polyaddition of oligomeric polyisocyanates with polyol components, or from high molecular mass adducts which are further cross-linked by physical drying or other mechanisms. The nature of the isocyanate building blocks (aliphatic or aromatic) and the structure of the backbone are important. Film mechanical properties are dependent on the structure of the polymer (segmented, interpenetrated networks) and cross-link density. PUR coatings are available solvent-borne and, as a result of the trend to reduced emission systems (low VOC), as high-solids, waterborne, solvent-free, and powder systems. Important PUR systems are summarized below.

Two-component coatings are the most important (solvent-borne) PUR paint systems. The primary component is always polyisocyanate (mainly HDI, IPDI, or TDI derivatives). The other component consists of polyols (polyester, polyacrylic) or amines or a mixture thereof and any additional ingredients such as pigments or solvents. The reactive components must be kept separate. Mixing, preferably of an equimolar equivalent, is done immediately before application. The coatings system can be applied by all conventional coating methods, but preferably by spraying or, industrially, with automatic two-component equipment. The solids contents of the coatings are usually higher than with standard coatings and can reach 80 % (pigmented high-solids), depending on the formulation. Curing takes place at ambient temperature, but can be accelerated by heat. Outstanding film properties such as high mechanical resistance, high chemical resistance, and, with aliphatic polyisocyanates, excellent lightfastness and weather resistance, open up a broad range of uses. Major areas of application are transportation (large motor and rail vehicles, aircraft, automobile finishes and refinishes), the building sector (wood and mineral substrates), industrial paints, and steel construction.

One-component coatings include air-drying and stoving systems. The most important are solvent-borne, isocyanate-terminated prepolymers of higher molecular weight made from aromatic or aliphatic isocyanates (MDI, TDI, HDI, IPDI) with polyols. They react with atmospheric moisture to form urea linking groups. Although the final properties are comparable to those of two-component PURs, curing of these systems is slower, which limits their use mainly to wood-flooring coatings, corrosion protection, and applications on mineral surfaces.

The reaction of TDI or IPDI with polyol-modified drying or semi-drying oils generates urethane alkyds, which can be cured oxidatively (by air drying) like alkyds.

The isocyanate groups of prepolymers can be reacted with agents containing, e.g., acidic CH or NH groups to form blocked isocyanates (see Section Blocked Isocyanates). Their mixtures with polyols are stable at room temperature, but react at elevated temperatures (120–220 °C, depending on the nature of the blocking agent). The resulting films have a very high mechanical resistance. They are particularly important for automotive finishes, industrial goods and coil coating.

Powder coatings consist of a combination of solid polyols (mostly polyester or polyacrylate polyols) and solid blocked polyisocyanates as the cross-linker. ε-Caprolactam was the most commonly used blocking agent but is being replaced by other blocking agents. An alternative method, avoiding the use of an added blocking agent is the dimerization of the isocyanate groups to uretdiones. During stoving (10–25 min at 150–210 °C) isocyanate groups are liberated and undergo cross-linking. PUR powder systems are used in many industrial applications.

Waterborne coatings are growing continuously in importance, due to the requirement that emissions should be reduced. A variety of systems are available, comparable to solvent-borne coatings. One-component systems are based on self-emulsifying polyurethane or polyurethane-polyurea dispersions. They are manufactured by processes which allow the production, in contrast to solvent-borne PURs, of any molecular weight without having a significant impact on viscosity, and with only small contents of solvents or no solvent at all. These products are used in physically dried films for more flexible substrates like textile, paper, and plastics. One-component polyurethane/polyacrylate dispersions based on aliphatic or aromatic isocyanates are used for coating parquet flooring. In addition, UV-curing PUR acrylate dispersions are used in industrial wood and furniture finishes.

One-component stoving systems contain blocked polyisocyanates emulsified in OH- or NH-containing dispersions (epoxy polyester, acrylic). Important applications are automotive coatings (electrodeposition coating, primer surfacer) and other industrial coatings.

Reactive waterborne two-component systems are based on polyisocyanates (HDI, IPDI) and aqueous OH-functional dispersions (polyacrylate, polyester, polyester polyurethane). Self-emulsifying polyisocyanates reduce interfacial tension between the components and ease homogenization. The film properties are influenced by the extent of side reactions, which can occur in the presence of water. The main applications of these reactive systems are in all types of industrial, wood, and plastic coatings.

[Top of Page]

10. Polyurethane Adhesives [202-204]

Herbert Blankenheim

See also ⟶ Adhesives

PUR adhesives exhibit unique properties due to their wide variety of compositions, their excellent adhesion to most polar substrates (ability to form hydrogen bonds), and the possibility of chemical cross-linking.

To achieve good cohesive strength of the adhesive bond, high molecular weight polymers are necessary. On the other hand, for good adhesion to the substrate, efficient wetting of the surface is essential. This can be done either by "liquefying" the polymer by the use of solvents, aqueous dispersions, or heat or by in situ polyaddition of low-viscosity polyols and polyisocyanates to give high molecular weight products. Depending on the application, the adhesives can be differentiated as follows:

Solvent-borne adhesives are made by dissolving granules of a linear high molecular weight OH-terminated PUR in a solvent like methyl ethyl ketone, acetone, ethyl acetate, or mixtures thereof to a solids content of up to 15–20 %. The PUR building blocks are crystalline polyester diols or polycaprolactones, aromatic diisocyanates (mainly MDI or TDI), and possibly a low molecular weight chain extender like butanediol or hexanediol. After evaporation of the solvent a nonblocking adhesive film results on the substrate. Due to the crystalline nature of the polyester soft segment, this adhesive film can be thermally reactivated at temperatures between 50 and 80 °C, and in this tacky state bond formation to a second coated and activated substrate can be achieved. On cooling down again, recrystallization leads to high initial and final bond strength ("physical setting"). To improve properties such as heat resistance, resistance to solvents, water, oils, or plastisizers, two-component processing is possible. This is achieved by adding a solvent-based triisocyanate (e.g., Desmodur R-Series, Bayer MaterialScience, cf. Section Aromatic Polyisocyanates) to the adhesive solution shortly before application, which results in chemical cross-linking by reaction with the OH groups of the base polymer and other isocyanate-reactive groups on the substrate (including water). The main application for this kind of adhesive is in the footwear industry (bonding shoe soles to uppers).

Waterborne adhesives usually consist of a 40–50 wt. % aqueous dispersion of a high molecular weight PUR made by the acetone or the prepolymer mixing process. Besides crystalline polyester diols, aliphatic isocyanates such as HDI or IPDI and ionic or hydrophilic groups containing chain extenders are used as starting materials. Properties and processing are comparable to those of solvent-borne adhesives. Cross-linking can be achieved by using solvent-free emulsifiable polyisocyanates (e.g.- Desmodur D series, Bayer MaterialScience). The main applications are in sport shoe fabrication, the furniture industry (MDF kitchen cabinet door lamination with PVC films), and the automotive industry (lamination of interior trim parts with films).

Hot-melt adhesives are available in nonreactive and reactive form. The starting materials for nonreactive systems are similar to those used for solvent-borne adhesives, but instead of dissolving the granules, these are either directly extruded onto the substrate or (co)extruded to form hot-melt films or fleeces. Another possibility for bringing the adhesive polymer into intimate contact with the substrate (without using solvents or water as a carrier) is cold grinding of the granules. The resulting powders (particle size < 600 µm) can be easily brought onto the surface by scatter coating. Common to all these nonreactive hot melt application forms is the (in this case only one-component) processing by the thermo-activation procedure described above. Application fields are textile and film lamination.

Reactive hot melts are prepolymers of a crystalline or high-T_g polyester with an excess of a diisocyanate (mostly MDI-based). They are applied at temperatures of 60–80 °C higher than the melting point of the soft segment and combine the aforementioned advantages of physical setting and chemical cross-linking (NCO/water reaction). Typical application areas are bookbinding, woodworking, packaging, and the automotive and construction industries.

Reactive adhesives can be divided into one- and two-component systems. One-component reactive adhesives liquid at room temperature are NCO-terminated prepolymers of (usually) polyether polyols and an excess of an aromatic polyisocyanate (mainly MDI derivatives). Setting occurs by reaction with humidity and therefore requires at least one porous substrate. Applications are foam rebonding, rubber crumb bonding, and in the construction and transportation fields.

Two-component reactive adhesives consist of a liquid polyether polyol (or a low-viscosity polyester polyol) and a polyisocyanate (mainly polymeric MDI). The two components are either mixed and applied immediately before use by an automatic machine or by using a handheld double cartridge/static mixer combination. A broad spectrum of polyisocyanates and polyols is available, and the mixing ratio of the two components can be varied over a wide range. Thus, it is possible to design the adhesive for the individual substrate/bond requirements, e.g., from flexible to rigid. Application fields are again transport and construction, and flexible packaging/film lamination (no porous substrate necessary).

[Top of Page]

11. Polyurethane Fibers [205]

Wolfgang Friederichs

See also ⟶ Fibers, 4. Synthetic Organic – Polyurethane Fibers

Synthetic fibers containing at least 85 wt % of high molecular weight segmented PUR [206] are known as Elastane or in the USA as Spandex. The segmented structure (see Section Polyurethanes with Segmented Structure) gives these fibers high elasticity and makes them easy to stretch. The properties are determined not only by the raw materials used, but also by the synthesis conditions, the spinning process, and the post-treatment.

Compared to rubber fibers, the PUR fibers exhibit superior properties such as the ability to form fine filaments, good colorability and chemical resistance, and high resistance to physical impact.

They are produced by a two step process. In the first step, long-chain diols are reacted with aromatic diisocyanates; in the second step, the high-melting urethane and/or urea groups which are necessary for the high-level properties are introduced by chain extension with short-chain diols or diamines (see Section Polyurethanes with Segmented Structure) [207-211].

In industrial production, usually poly(tetraethylene glycol) [212, 213], manufactured by ring-opening polymerization of tetrahydrofuran, is used as the long-chain polyol. In some cases, copolyethers of tetrahydrofuran and 3-methyltetrahydrofuran are used [214]. If polyesters are used as diols, they are usually based on adipic acid and mixtures of ethylene glycol, propylene gylcol, butylene glycol, and/or 1,6-hexandiol.

Aromatic diisocyanates, mainly 4,4′-MDI and in some cases 2,4-TDI, are used exclusively. Due to its unsymmetrical structure, 2,4-TDI leads to a weaker segmented structure and therefore to lower thermostability. Aliphatic diisocyanates, e.g., HDI, are only used in small amounts as modifiers.

Chain extension with diamines usually gives high-performance Elastane [215-218]. Mostly primary cycloaliphatic or aliphatic diamines such as ethylenediamine and 1,2-propylenediamine are used. Modification of the hard segments is achieved by adding small amounts of, e.g., 1,3-diaminocyclohexane.

12. Polyurethanes and Isocyanates as Binders [219]

Donald-Richard Larimer

Panels and molded parts made of wood chips, fibers, and veneers are used extensively in the furniture, building, packaging, and automotive industries. These products are produced under heat and pressure by using a variety of organic binders. PURs are excellent starting materials for composite binders and are used extensively in their production. They are classified according to binder type as polyurethane and polyurea bonding agents.

Polyurethane bonding can be accomplished with one-component moisture-curing systems or two-component ambient-cure systems. The latter can be adjusted in reactivity to meet processing conditions.

PUR dispersions are also utilized in special cases. In addition to adhesion, PUR dispersions exhibit excellent film-forming properties. This is an especially important characteristic for the sizing of glass fibers. PUR dispersions meet very specific requirements regarding film formation and glass adhesion, critical for “matrix” bonding. The properties of glass-reinforced plastic depend to a high degree on the adhesion of the polymer to the surface of the glass fibers.

In polyurea bonding, polyisocyanates are transformed into polyureas at high temperatures in the presence of moisture and, if necessary, catalysts. In addition to the physical adhesion properties of polyureas, there is also the possibility of adhesion by way of chemical reactions between polyisocyanate and reactive groups of the substrate material. Compared to the PUR binders, polyureas are more rigid and hydrophobic.

Binders based on polymeric diphenylmethane diisocyanate (PMDI) have been industrially used in the wood composite industry since 1973. PMDI binders are used worldwide in the manufacture of particleboard, oriented strand board (OSB), laminated strand lumber (LSL), medium-density fiberboard (MDF), and other specially engineered wood composites, as well as panel products based on annual plants, e.g., straw and sugar cane bagasse. The manufacture of straw-based panels was indeed first made possible with PMDI binders.

The success of PMDI binders in the wood and straw composites industry has its origin in the unique properties of the polyurea bond.

Moisture resistance: polyurea is highly cross-linked, chemically stable, and hydrolytically resistant. PMDI binders are one of two binders listed in the European standard for particleboard EN 312-3/5, option 2 that require no special testing to prove hydrolytic resistance.

Dimensional stability: polyurea is also hydrophobic and lends wooden panels improved dimensional stability. This was demonstrated on particleboard during three years of outdoor exposure, where they showed the lowest moisture absorbance and weight changes. This favorable behavior was also confirmed by long-term stress bending (creep testing) under severe conditions of 40 °C and 95 % R.H.

Emission-free: PMDI wood binders contain no formaldehyde. The resultant polyurea bond in the finished panel is free from emissions.

High-strength properties: The excellent adhesion properties of polyurea and the deep anchoring of the bond in the wood structure leads to the high strengths of the different wood composite panels.

During the manufacture and processing of rigid PUR foams, cutting and milling about 5–25 % of scrap is generated. Utilization of this scrap is possible by bonding it into panels or molded parts with varying properties. This can technically be realized with the aid of the hot-press technique employing PMDI binders, analogous to the manufacture of wood composites. The physical and mechanical properties of articles made from rigid PUR foam scrap can be varied over a wide range. The properties depend upon the type and pretreatment of the raw material, the amount of bonding agent, and the density.

Cork granulates and remilled rubber waste, especially peeled tire tread from the recapping process, as well as recovered scrap from milling of frozen old tires, can be converted with PUR bonding agents to composite materials. The bonding

agents are isocyanate-terminated, one-component, moisture-curing prepolymers or reactive two-component systems. They form elastic films during curing. The prepolymers are synthesized from long-chain linear or slightly branched polyethers and MDI types or toluene diisocyanate and/or from mixtures of both. The one-component prepolymers generally have an NCO content of ca. 10 % and a viscosity of 1500 to 3000 mPa · s at 23 °C.

The most important properties are elasticity, flexibility, damping capacity and void content. They can be varied over a broad range through the shape and size of the rubber particles, type and amount of binder, and degree of compaction.

[Top of Page]

13. Special Products

Wolfgang Friederichs

PURs are particularly suitable as wall materials for microcapsules (see also ⟶ Microencapsulation). Capsules can be impermeable or permeable to the core material. The capsule wall is usually produced by interfacial reaction of multifunctional isocyanates or NCO prepolymers and multifunctional amines at an oil/water interface. The microcapsules have a diameter of 1 to 5000 µm, depending on the droplet size of the emulsion used for polymer formation. The capsules are used for a wide variety of purposes, e.g., for the production of carbonless copying paper or for the delayed release of plant-protection products.

Polyoxazolidinone polyisocyanurates are produced from polyisocyanates and epoxy resins in the presence of special catalysts (see Chap. Basic Reactions). They have high fire resistance, high long-term heat resistance, and excellent electrical insulation properties [220, 221].

Water-soluble PURs are of interest as retaining agents and dyeing auxiliaries, thickeners, paper-sizing agents, and other sizers.

Oligourethanes with unsaturated (e.g., acrylate) groups can be cured by UV radiation in the presence of photoinitiators [222]. Systems based on acrylate groups containing blocked NCO prepolymers have been developed. They can be cured either by heat or by radiation (dual curing [223-227]) and are used especially for automotive refinishing paint.

14. Safety and Ecology

Manfred Giersig, Eckehard Weigand, Michael Halfmann, Friedrich-Wilhelm Wittbecker

PUR-containing products have become an essential part of modern living. For production and processing of all of these varieties of PUR, it is estimated that worldwide well over 500 000 people are handling PUR raw materials every day. For the toxicology of the raw materials, see also ⟶ Isocyanates, Organic – Toxicology and Occupational Health and ⟶ Polyoxyalkylenes – Toxicity .

Health, safety, and environmental aspects, especially for MDI and TDI (see Section Aliphatic Polyisocyanates), are described in [228].

14.1. Safety Precautions when Handling the Raw Materials

When building and operating plants for producing PUR, all laws, decrees, and regulations in force for chemical plants must be observed. Many years' experience in handling the raw and auxiliary materials for PUR has shown that these products can be handled safely. It is a prerequisite for this, however, that the persons working with them are supplied with all the necessary information and above all, that the required technical and personal protective equipment is available and used.

All isocyanates, activators, and most alkanes and haloalkanes are regarded as products having acute or chronic harmful properties.

Di- and polyisocyanates have only a moderately acute oral and cutaneous toxicity. Di- and polyisocyanates are known to have allergenic potential, and the human health risk due to the acute or chronic effect of isocyanate vapors and aerosols (of liquid and dust forms) is considerably higher. Therefore, it is of extreme importance that appropriate safety measures, e.g., protective clothing and ventilation, are provided.

Occupational exposure limits have been set in many countries. As examples, the currently (2003) MAK values for Germany are listed in Table 11.

Table 11. German air concentration limits (according to TRGS 900) for typical polyisocyanates (see Section Polyisocyanates)

Isocyanate	Air concentration limit	
	ppm	mg/m^3
TDI (2,4-/2,6-)	0.005	0.035
MDI	0.005	0.050
NDI	0.010	0.087

HDI	0.005	0.035
IPDI	0.010	0.092
H12-MDI	0.005	0.054

The vapor pressures of the industrially most important isocyanates at their usual processing temperatures are listed in Table 12.

Table 12. Vapor pressures of the industrially most important isocyanates at processing temperature

Isocyanate	Processing temp., °C	Vapor pressure, Pa	Conc. of saturated vapor, mg/m^3
TDI (2,4-/2,6-)	25	3	255.5
PMDI	25	$< 10^{-2}$	< 0.1
MDI	42	6×10^{-2}	0.65
NDI	130	ca. 120	7850

Many years' experience in handling the various isocyanates has shown that very effective air-extraction systems must be present at all workplaces where TDI is processed at room temperature or MDI and NDI at temperatures above 40 °C. If, for any reason, the aforementioned maximum value at the workplace is exceeded (e.g., on construction sites), the persons present in the working area must be protected against inhaling isocyanates, wherever possible by wearing suitable masks. TRGS 430 is a special German guideline on how to analyze and monitor isocyanates at workplaces where PURs are produced or processed.

More information can be obtained from literature available from the isocyanate producers, or their associations e.g.,

ISOPA: http://www.isopa.org
API: http://www.polyurethane.org/

Polyols have been well studied with respect to their toxicity and, if used according to relevant regulations, do not present an industrial hygiene problem. Aminopolyethers are moderately irritating to the eyes and skin, and thus contact with them should be avoided.

Auxiliary Materials. The ready-to-use polyol preparations, which are used to a large extent nowadays, contain the auxiliary materials necessary for PUR production (especially activators, emulsifiers, and stabilizers) in quantities of up to ca. 1.5 wt %. Toxicological studies have shown that these small quantities of the auxiliary materials scarcely affect the biological behavior of the polyols.

Polyols and polyol preparations have an exceptionally low vapor pressure; a health hazard via inhalation is therefore not to be expected. If, however, they contain readily volatile aliphatic amines as activators, an unpleasant odor can be expected.

For the *tertiary amines* used as catalysts, occupational threshold values in air (MAK) defined by the German TRGS 900 (2003) are available only in some cases, e.g., triethylamine: 1 mL/m^3 (ppm) corresponding to an eight-hour average value of 4 mg/m^3. However, the intense odor of most tertiary amines gives a clear warning of excessive concentrations.

Low-boiling chlorofluoroalkanes were used as blowing agents for producing rigid and flexible foams in the past. Since these substances are suspected of damaging the ozone layer, their use was phased out in the late 1980s. These substances have therefore been replaced by alkanes and to some extent by partly halogenated alkanes, because the blowing process cannot be carried out with carbon dioxide (from the NCO/H_2O reaction) in all cases. Since direct contact of partly halogenated alkanes and alkanes with the skin leads to intense defatting and roughness, it is important to wear impermeable gloves and to take good care of the skin. The inhalation of vapors from these blowing agents in high concentrations can lead to intoxication.

14.2. Emissions, Accidental Release, and Waste Disposal [229]

The emission of PUR raw materials into the atmosphere during production and processing is usually small. In special cases (e.g., filling of storage tanks, flexible foam slabstock production), measures to reduce emissions are advisable or required. Since a certain concentration limit of a harmful substance must not be exceeded in the air at the workplace, the air is extracted at the processing plant, and this is one source of emissions. The volatility of the raw materials determines the extent of emission. Hence blowing agents (e.g., carbon dioxide, halogenated hydrocarbons, hydrocarbons) and tertiary amines are the main constituents, whereas isocyanates normally do not play a significant role. Since the carbon dioxide formed from the reaction of water with isocyanate is a natural constituent of air, it presents no problem. The other blowing agents are discharged into the atmosphere in varying quantities depending on the foam type. The emissions of volatile organic chemicals are being increasingly regulated in industrialized countries. National regulations must be observed.

During storage, tank-filling, and transportation of PUR raw materials, discharge due to accidents or leaks cannot be entirely ruled out. Should this happen, as a standard precaution, the accidentally released raw material should be prevented from entering soil or water by suitable measures (e.g., covering sewers). Spilled product should be covered with

a liquid-binding material such as a chemical binder based on hydrated calcium silicate (e.g., Hybilat), sand, or sawdust. This can then be transferred to a waste container. In the case of spilled isocyanates, the liquid-binding material should be moist and the material in the waste container stored under moist conditions in a secure place in the open air. The lid of the container must not be tightly sealed because of danger of bursting (CO_2 evolution). The polluted areas must then be decontaminated (see below). In all cases, the waste collected in the containers is best disposed of by incineration in a suitable facility (see below). In the unlikely event that a large pool of escaped isocyanate has formed, all unauthorized persons should be kept away from the scene of the accident. Persons downwind should be evacuated. Further evaporation of isocyanate can be prevented very effectively by covering the pool with protein foam. Large quantities of liquids can be pumped into waste containers, before the procedure given above is applied to the remaining residues. Nevertheless, in the case that isocyanate raw materials have leaked into the soil or water, inert polyurea is the major end product of their reaction with water. According to a three-month soil study with ^{14}C-labeled TDI and MDI, degradation products (e.g., amines) were at no time detected in the aqueous extract.

An experimental pond study indicated low environmental risk arising from spillage of polymeric MDI into a natural aquatic ecosystem. No direct ecotoxic effects and no bioaccumulation of MDI or MDA were observed. Furthermore no MDI or MDA could be detected in water.

Waste Disposal. Liquid or solid PUR production wastes which are not completely reacted are categorized as hazardous waste and should not be dumped but burned in industrial waste incineration facilities, equipped with state-of-the-art flue-gas scrubbing.

Drum decontamination. Any isocyanates residue in “empty” containers that are to be sent for reconditioning or disposal can be rendered harmless with a special neutralizing solution (for formulations, see the specialist literature). The same solution can also be used to decontaminate clothing, equipment and floors. Fully cured PUR end-product wastes, such as trimming waste from flexible foam slabs, can be recycled or recovered (see below). Wastes for which no utilization is yet possible can have their energy content recovered in appropriate incineration plants or can be disposed of in landfill sites, as a last resort (and as long as local regulations do not exclude organic materials from landfilling).

14.3. Recycling/Recovery of Polyurethanes

Because of their excellent durability, PURs in general contribute significantly to a long service life of the products containing them. This is an important contribution to waste minimization. To handle PUR wastes that cannot be prevented, technologies for recycling or recovery have been developed by many industrial associations, joint ventures, and cooperations between producers and users of raw materials throughout the world, e.g., the Polyurethane Recycle and Recovery Council (PURRC, USA), European Isocyanate and Polyol Producers Association (ISOPA, Europe), Tecpol (Germany), and the Japan Urethane Industrial Institute (JUII, Japan). The most appropriate method may vary from case to case, and depends on the properties of the PUR, the intended application, and the related capacity of the market for the recycled material, and very much on logistical, economic, and ecological factors. After all, recycling should not only serve to minimize waste; it ought to contribute also to the saving of resources and to the reduction of environmental burdens. Only then can recycling be counted as a contribution to sustainable development. Currently, the following possibilities for recycling/recovery of PUR exist.

Mechanical Recycling. Mechanical (or physical) recycling of PURs means one of the many forms of “particle recycling.” The rebonding of flexible foam or adhesive pressing of rigid foam, for example, involves binding roughly 90 wt % of particles with about 10 wt % PUR binders under heat and pressure. Particle bonding uses up to 70 wt % PUR as the matrix for any kind of particles (e.g., rubber chips for sports ground surfaces). PUR powder can be incorporated into new PUR articles at a loading of round about 20 wt %. PUR powders/particles are also being reused as oil binders.

Feedstock Recycling/Chemical Recycling. Large-scale feedstock recycling processes recover oil and gas products from mixed plastic waste streams of a hundred thousand tons per year or more, of which PUR materials can be one constituent. These processes include pyrolysis, hydrogenation, synthesis gas generation, and reduction of iron ore in blast furnaces. When smaller, but pure streams of particular polymers are available, “chemical recycling” processes can be applied. It is thus possible to obtain liquid degradation products from PURs that are suitable, together with new material, for the manufacture of new PURs. For example glycolysis has been applied more often in favorable case where a suitable application for the glycolysate has been identified. Much research has resulted in several process variations [230]. Some of them include purification and chemical processing of the regenerate before use in PUR applications. Observation of appropriate industrial hygiene and safety is essential, because hazardous substances could be formed.

Energy Recovery. Combustion, or incineration with the recovery of energy, is currently the most effective way to reduce the volume of organic material which otherwise would have to be sent to landfill. Combustion is suitable for all materials for which material recycling is ruled out on ecological or economic grounds or simply because of logistical difficulties. Rotary kilns, fluidized beds, and mass burning equipment, for example, have been shown to be suitable for combustion of plastic scrap. These processes are applied, e.g., in cement production, in industrial power stations, and in municipal solid waste combustors. The heat content of PURs (lower heating value 24–30 MJ/kg) is comparable to that of coal. Numerous test runs have shown that this energy content is recovered in an environmentally sound manner in modern plants equipped with state-of-the-art flue-gas treatment facilities.

14.4. Fire Performance of Polyurethanes [128], [231]

The fire performance of a product is characterized at the various stages of a fire by the parameters ignitability, flame spread, and heat release, and by phenomena such as smoke density and the toxic potency of the combustion products. The dripping behavior, the amount of debris in general, and the corrosive effect of effluents are also determined. Fire test methods differ greatly from country to country, and also depend on the field of application. Different requirements exist, e.g., for the electrical, transportation, furniture, and building sectors. Fire testing, classification and regulatory requirements are very complex and reference must be made to summarizing literature.

In general, the fire hazards posed by a PUR foam and its fire effluents are comparable to those of natural materials like wool and wood. The chemical composition of the material is not the main determining factor. The behavior of the material in fires depends on, e.g., the relative surface of the material (e.g., massive wood compared to sawdust), the combination of materials, thermal conductivity, nature, duration, and intensity of ignition sources, and ventilation.

The qualitative and quantitative composition of fire effluents depends on the decomposition conditions (temperature and ventilation) as well as the amount of material involved. Comparative tests taking into account different stages of a fire have confirmed that the toxicity of fire effluents from PUR products is similar to that of other natural products like wood, cork, and wool. Fire effluents of natural and artificial organic products always pose a toxic hazard irrespective of the type of burning material.

As effluents from PUR do not differ greatly from natural materials, a similar effect on the environment is assumed. Due to their reactivity, isocyanates are rapidly decomposed photochemically or converted chemically.

A special fire risk from PUR is not evident: risk of ignition and flame spread as well as emissions mainly depend on the scenario and the amount of burning material, and are not determined by the specific material involved.

15. Economic Aspects

Geza Avar

Even though PUR makes up only for ca. 6 % of the total consumption of plastics, the annual production reached the 10 × 10^6 t level in 2004. The growth rate since 1970 (Fig. 40) on average exceeded 5 % and thus grew faster than GDP. The fastest growing market over the last few years was Asia, in particular China with growth rates exceeding 10 %.

Figure 40. World PUR consumption

Figures from 2001 show that there is still a big difference in per capita consumption between the regions (Fig. 41), which allows an optimistic outlook for further development.

Figure 41. PUR per capita consumption 2001 by regions

Figure 42 gives an overview of the main application areas of PURs and Figure 43 the split for the basic raw materials MDI, TDI, and polyethers.

Figure 42. World PUR consumption 2004 by applications (total: 10 × 10^6 t/a)

Poly(Vinyl Chloride)

General aspects of polymers, properties and testing, processing, additives, and analysis are discussed in Plastics, General Survey; Plastics, Properties and Testing; Plastics, Processing; Plastics, Additives; and Plastics, Analysis, respectively. States of order are treated in Plastics, Properties and Testing. Fundamental aspects of polymerization reactions are treated in Polymerization Processes.

Michael W. Allsopp, Independent PVC Technology Consultant, Heswall, Wirral, England (Chaps. 1 – 3, 5 – 10, Section 4.1, 4.2, 4.4)

Giovanni Vianello, European Vinyls Corportaion (IT), Porto Maguero, Venice, Italy (Section 4.3)

1. Introduction

Poly(vinyl chloride), PVC, a polymer prepared from vinyl chloride monomer (VCM),

where $n = 700 - 1500$, holds a unique position amongst all the polymers produced today. It is relatively inexpensive and is used in such a wide range of applications that its versatility is almost unlimited. However, if it were discovered today it would probably be shelved as a somewhat intractable and thermally unstable material. How can this apparent contradiction be explained?

The uniqueness of PVC can be considered under three headings: morphology, versatility, and molecular structure.

1.1. Morphology

As made, PVC is particulate in nature and comes in two main sizes depending on the process used. Suspension and mass polymerizations give grains (particles) of 100 – 180 µm in diameter, whereas the emulsion process affords a latex of particle size 0.1 – 3.0 µm. The latter is dried to yield friable grain-like structures of 5 –50 µm.

Because of this unique particulate structure the most frequently used word in the vocabulary

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a21_717

of the PVC technologist is morphology. In no other polymer is it as important as it is in PVC.

In its polymerisation, a growing PVC chain becomes insoluble in VCM above a chain length of about 10 units [6] so PVC is essentially insoluble in its monomer and the process is thus classified as a precipitation suspension polymerization. However, PVC is heavily swollen and partly solvated by the monomer to the extent of 27 wt % [7] and this has a major influence on the polymerization itself (see Section 4.1) as well as the final properties and end uses of PVC. Hence, the way the PVC separates from the monomer, its future growth mechanism, and the swelling of the polymer by the monomer are critically important in its formation, handling, and subsequent processing.

1.2. Versatility

Poly(vinyl chloride) is a generic name. Each producer makes a range of PVC polymers which vary in morphology and in molecular mass, depending on the intended end use. In industry, the K-value and viscosity number are used to represent molecular mass, and producers often reflect these parameters in the grade codes used to define different products (e.g., S 68/173 refers to a suspension type material with a K-value of 68, and VY 110/57 to a resin with a viscosity number of 110). The calculation of the K-value is given in [8] and the relationship between these parameters and molecular mass in [9].

PVC with K = 66 – 68 can be processed in rigid formulations to give pipes, conduit, sheet, and window profiles; K = 65 – 71 in flexible formulations for flexible sheet, flooring, wallpapers, cable coverings, hoses, tubing, and medical products, and PVC with low K-values (55 – 60) in formulations for injection molding of pipe and conduit fittings, integral electrical plugs, and blow molding of bottles and other containers.

In contrast, poly(methyl methacrylate) of even very high molecular mass is still soluble in its monomer and produces only glasslike solid beads at the end of polymerization which have no internal morphology and as such are limited to a narrow range of end uses (e.g., moldings for optical applications such as covers for car lights and illuminated signs.

1.3. Molecular Structure

Amongst the range of polymeric materials produced today PVC is unique because the bulky chlorine atom imparts a strongly polar nature to the PVC polymer chain, and the essentially syndiotactic conformation of the repeat unit in the chain leads to a limited level of crystallinity [10]. This results in good mechanical properties, particularly stiffness at low wall thickness, high melt viscosity at relatively low molecular mass, and the ability to maintain good mechanical properties even when highly plasticized. This enables a wide range of softness and flexibility to be achieved and hence leads to an even wider variety of end uses.

2. Physical and Chemical Properties

2.1. Vinyl Chloride Monomer (VCM)

Vinyl chloride monomer (VCM), *bp* − 13.4 °C, is a gas at room temperature and pressure. Therefore, it is handled as a compressed volatile liquid in all polymerization operations. Its vapor pressure over the typical polymerization temperature range of 50° to 70 °C is 800 – 1250 kPa. As a result PVC polymerization reactors are thick-walled jacketed steel vessels with a pressure rating of 1725 kPa. VCM is slightly soluble in water (0.11 wt % at 20 °C). Whilst this has some influence on the suspension polymerization process it is critically important to the success of the emulsion polymerization process described in Section 4.3. The polymerization of VCM is strongly exothermic, and its specific heat and heat of evaporation of 1.352 kJ kg^{-1} K^{-1} and 20.6 kJ/mol, respectively, allow the use of a condenser to remove the heat of reaction as well as by the more conventional jacketed vessel systems. Its explosive limits in air are 4 – 22 vol % and plant design, particularly when handling unreacted VCM in the recovery system, must be designed and operated accordingly.

Further physical and chemical properties of VCM are given in → Chlorinated Hydrocarbons, Chap. 3.1.1.

2.2. Poly(Vinyl Chloride) (PVC)

PVC is never used alone. It is always mixed with heat stabilizers, lubricants, plasticizers, fillers, and other additives to make processing possible, all of which can influence its physical and mechanical properties. Table 1 lists properties of rigid (unplasticized) PVC with a total additives content of <10 %. Table 2 list properties of flexible (plasticized) PVC where the range of physical properties varies widely, depending on the plasticizer content. This can vary between 20 and 100 phr so as a guide properties typical of a plasticizer content of 50 phr are given.

Table 1. Typical properties of rigid PVC (UPVC)

Property	Test	Value
Tensile strength at 23 °C, MPa	BS 2782 : 301G ISO R527	55
Tensile modulus (1 % strain, 100 s), GPa	BS 4618 ISO R899	2.7 – 3.0
Tensile modulus (1 % strain, 3 years), GPa	ISO R899	1.7
Izod impact, ft lb/in	BS 2782 : 306A ISO R180	2 (unmodified) 10 (modified)
Specific gravity	ISO R1183	1.38 – 1.45
Coefficient of linear thermal expansion, K^{-1}	BS 4618 : 3.1	6×10^{-5}
Coefficient of thermal conductivity, W/mk		0.14
Flammability (oxygen index)	ASTM D2863 (Fenimore Martin)	45
Weathering resistance		very good (especially white)
Resistance to concentrated mineral acids (at 20 °C)		excellent
Maximum continuous operating temperature	field experience	60 °C

Table 2. Typical properties of flexible PVC

Property	Test	Value
Specific gravity	ISO R1183	1.19 – 1.68
Tensile strength, MPa	BS 2782.320A	7.5 – 30
Elongation at break, %	BS 2782.320A	140 – 400
BS softness	BS 2782 365A	5 – 100
Cold flex temperature, °C	BS 2782 159B	− 20 to − 60
Volume resistivity at 23 °C, Ω · cm	BS 2782 202A	$10^{10} - 10^{15}$
Ageing resistance	field experience	excellent
Ozone resistance	field experience	very good

In addition the K-value (molecular mass) of the PVC can also influence properties significantly (see Section 4.1.4.3).

PVC has extremely good chemical resistance to all but low molecular mass chlorinated solvents. Therefore, it is widely used in the construction and lining of chemical plants.

3. Resources and Raw Materials

VCM is produced industrially by two main reactions:

1) Hydrochlorination of acetylene
2) Thermal cracking of 1,2-dichloroethane produced by direct chlorination or oxychlorination of ethylene in the balanced process. Presently, more than 90 % of the VCM produced is based on this route, full details of which are given in →Chlorinated Hydrocarbons , Chap. 3.1.

In an ideal situation a PVC plant is fully integrated, beginning with ethylene and chlorine (salt), but various levels of integration are employed worldwide. Stand-alone PVC plants, supplied with VCM by sea, road, or rail, are well known as are ones making the bulk of their VCM requirements from scratch on site, with supplementary supplies of 1,2-dichloroethane for cracking to satisfy peak demand. Finally, there are fully integrated plants which have the benefit of uninterrupted supplies of base raw materials (ethylene and salt) and where the monomer is supplied by pipeline at a significant cost benefit. It can cost up to 65 Euro/t to transport VCM within continental Western Europe depending on distance and type of freight used, i.e., road, rail or ship.

4. Production

There are three main processes used for the commercial production of PVC: suspension (providing 80 % of world production), emulsion (12 %) and mass, also called bulk (8 %).

4.1. Suspension Polymerization of Vinyl Chloride

4.1.1. Introduction

The layout of a typical suspension PVC plant is shown in Figure 1.

Figure 1. Suspension PVC plant
a) Reactor; b) Blowdown vessel; c) VCM recovery plant; d) Stripping column; e) Heat exchanger; f) Centrifuge; g) Driers

The suspension polymerization process is essentially a bulk polymerization process carried out in millions of small "reactors" (droplets). Liquid vinyl chloride under its autogeneous vapor pressure is dispersed in water by vigorous stirring in a reactor (autoclave) of 25 – 150 m^3 capacity, fitted with a jacket and/or condenser for heat removal and baffles for optimum agitation. This results in the formation of droplets of average diameter 30 – 40 µm which are stabilized against coalescence by one or more protective colloids (granulating agent). The other essential ingredient is a monomer-soluble free radical initiator.

The formulations charged to the reactors (otherwise known as autoclaves, kettles, or polymerizers) are normally referred to as recipes. A basic recipe for suspension processes can be simply water, VCM, initiator, and suspension agent, for example:

VCM	100 parts
Water	90 – 130 parts
Protective colloid	0.05 – 0.15 parts
Initiator	0.03 – 0.08 parts

These quantities vary depending on the PVC grade, reactor size, plant type, etc.

Whilst this will produce a particulate PVC it is unlikely to have the optimum morphology. This will only be achieved if other additives are employed, such as oxygen, buffers, secondary or tertiary granulating agents, chain-transfer or chain-extending agents, comonomers, antioxidants, together with the right level of agitation and homogenization and the correct charging procedure and timing for each additive addition. A combination of just the right number and degree of the above parameters to achieve the optimum morphology usually determines the quality of a PVC grade.

Figure 2. Reaction profile for a typical suspension polymerization
a) Pressure; b) Batch temperature; c) Jacket temperature

After charging, the reactor contents are heated to the reaction temperature of 45 – 75 °C. Reactors are 80 – 95 % full at this stage. Heat causes some of the initiator to decompose into free radicals, and the monomer in the droplets begins to polymerize. The strongly exothermic reaction (1540 kJ/kg) is controlled by removing heat via the jacket and/or by boil-off into a con-

denser from which the condensed monomer is returned to the reactor.

Progress of the reaction in a jacketed reactor can be followed by continuously monitoring the water temperature in the jacket since the flow rate is constant and a constant batch temperature is maintained by progressively reducing the cooling water temperature (see Fig. 2).

Although PVC is insoluble in its monomer (see Section 1.1) the polymer is swollen by ca. 27 wt % VCM to form a coherent gel [7]. Therefore, as the conversion increases towards 70 % and beyond, the pressure in the reactor starts to fall; slowly at first, but then much more rapidly as the last of the free liquid monomer is consumed. Polymerization continues in the gel phase, very rapidly at first since chain termination is hindered by lack of mobility of the growing chain, but, as conversion increases beyond 80 – 85 %, monomer starvation rapidly reduces the rate.

Figure 3. Stripping column

The reaction is terminated at a predetermined pressure by either adding a chain terminator and/or venting off the unreacted monomer to the recovery plant. After venting, the resin in the aqueous slurry can still contain 2 – 3 % unreacted monomer, which is removed by stripping, either batchwise (as in older plants) or continuously in a column. The batch is discharged from the reactor to a feed vessel and then fed continuously through a stripper column (Fig. 3). The unreacted monomer is recovered, liquified, and reused in later polymerizations. After passing through a heat exchanger the slurry is fed to a continuous centrifuge to give a wet-cake with 20 – 30 % moisture content. The remaining water is then removed by conventional flash and/or fluid-bed drying to give a dry, free-flowing powder with a residual VCM content below 1 ppm.

4.1.2. Additives

Water. The water used in the process should be demineralized (i.e., of low conductivity) since ionic species, especially sodium ions, can affect the performance of other additives such as protective colloids and influence final polymer properties such as volume resistivity.

Figure 4. The effect of the degree of hydrolysis of poly(vinyl acetate) on PVC grain properties
A) Grain porosity; B) Mean grain size

Protective Colloids (Granulating Agents). The protective colloids used in the suspension polymerization process are of two types: primary and secondary. The main function of the primary granulating agents is to control grain size, but they also affect porosity and other morphological properties. The demand for polymers with reduced residual VCM levels and better plasticizer adsorption led to the need for higher and more uniform porosity within each grain and this is achieved by using a secondary stabilizer in addition to the primary.

Although a wide variety of surface active materials have been or are still used, the substances most commonly used today are cellulose ether derivatives and partially hydrolyzed poly(vinyl acetates) or poly(vinyl alcohols) (PVAs). The latter are usually preferred and are used alone or in combination with the cellulose type, which they are gradually replacing. Typical PVA protective colloids are listed in Table 3.

As PVA primary granulating agents are prepared by alkaline hydrolysis of poly(vinyl acetates) they are complex mixtures containing fractions with different degrees of hydrolysis and molecular mass and having a block distribution of the OH groups [11]. Because of this complexity suspension processes need fine-tuning around the chosen agent since decreasing the average degree of hydrolysis of the PVA increases the porosity of the PVC grains and affects the grain size, as shown in Figure 4. This behavior is used in conjunction with agitation to achieve the optimum size and porosity. Below 70 % hydrolysis the PVAs are insoluble in water and lose their ability to stabilize the VCM droplets adequately so the normal range of PVA granulating agents used are in the range 70 to 85 %.

Many surfactants of low molecular mass have been claimed as useful secondary stabilizers but in practice few can be used without adverse side effects. One exception is the nonionic sorbitan monolaurate. Again, PVAs are much more widely used. However, this family is prepared by acid hydrolysis of low molecular mass poly(vinyl acetates) and has a random distribution of acetate groups [11]. Initially these materials, which are insoluble in water, were prepared as methanolic solutions (e.g., Polivic S 202) but more recently aqueous-based, low-hydrolysis PVAs (e.g., Alcotex A 55, and Polivic S 404 W), which are safer to handle and are environmentally more acceptable, have been developed and are now very widely used in the industry. Typical secondary protective colloids are listed in Table 3.

The use of secondary granulating agents affects the mean grain size and grain size distribution so the concentration of the primary must be adjusted to compensate. Since each producer uses autoclaves of different size and shape, equipped with different agitation and baffle systems, with or without condensers, and makes many different types of resin, no absolute formula is available which determines the magnitude of this change in primary concentration; this must be developed in-house by the suspension polymerization technologist.

Initiators. A range of initiators have been used, but currently a relative few are widely employed. At one time benzoyl peroxide and azo initiators were typically used, but diacetyl peroxides, peroxydicarbonates (PDC), and alkyl peroxyesters are now preferred. Typical initiators are listed in Table 4.

The half life $t_{1/2}$ at a particular temperature is the main factor which determines the choice of an initiator for a given PVC grade. The initiator should have a half-life of ca. 2 h at reaction temperature to optimize reaction time. Since the best plant output is obtained when the reaction profile is as square as possible (see Section 4.1.3) two initiators of different activity are often chosen to try to achieve this ideal. The more reactive initiator is used to start the polymerization but then as this exhausts itself the slower one takes over to completion. When preparing K 70 – 80 resins at temperatures at or below 52 °C, a peroxydicarbonate (e.g., **6**, **7**, **8** or **9**) is used as the primary initiator, with an active initiator such as **1** helping to bolster the slow initial rate which is obtained at these low temperatures. In the intermediate range of K 63 – 68 a single peroxydicarbonate (PDC) is usually sufficient, but at or below K 60 the PDC needs the extra radical flux of a slow initiator to prevent exhaustion of the reaction, so a less active diacyl peroxide such as **4** is used as a secondary.

Three other factors are also important: water solubility, storage and handling, and reactor fouling.

The initiators' water solubility can affect their efficiency by making them more susceptible to

hydrolysis and can affect their distribution between VCM droplets; the higher the solubility the more homogeneous the distribution.

The ease of storage and handling has a major influence on the acceptability of an initiator to a PVC producer. In general the shorter the half-life of the initiator, the more unstable it is, and the lower its self-decomposition temperature. The stability also depends on the radical energy and physical form. Solid crystalline initiators such as **8** (BCHPC) are more stable than their liquid analogues, e.g., **5** (EHPC). Many of the more active initiators must to be stored under refrigeration which tends to restrict their acceptability. Liquid initiators have the advantage that they can be automatically metered into reactors, which is

essential in larger computer-controlled plants. However, the trend is to use initiators as finely divided aqueous dispersions. This has the advantage of improving their homogeneity of distribution throughout the VCM droplets, allows them to be added at any time or temperature during the charging procedure, and renders them very safe to handle since their heat of decomposition is less than the heat of evaporation of the carrier. Dispersion of 25 – 40 % are typical, and systems must be carefully designed to ensure complete homogenization of the dispersion is maintained and accurate metering achieved. As the water soulbility of the initiator increases so does its tendency to cause reactor fouling. This is of increasing importance as more and more processes switch from the open to the closed mode of operation (see Section 4.1.4.4).

4.1.3. Kinetics

The kinetic profile seen in Figure 2 is typical of many VCM suspension polymerizations conducted at the lower end of the temperature range and exhibits the classical acceleration with conversion as shown by the gradually decreasing jacket temperature. At higher temperatures the reaction rate is more constant and a square-wave profile is obtained. Three different phases in the reaction can be identified:

Low Conversion (< 5 %). Polymerization occurs largely in the monomer phase because the quantity of polymer produced is so small. It is only this early stage that follows classical kinetics where the rate of polymerization is dependent on the square root of the initiator concentration:

$$\frac{-\mathrm{d}\,[\mathrm{M}]}{\mathrm{d}t} = \frac{k_\mathrm{p}\,[\mathrm{M}]\cdot k_\mathrm{d}\,[\mathrm{I}]^{1/2}}{k_\mathrm{t}}$$

where

[M] = monomer concentration
[I] = initiator concentration
k_p = propagation rate constant
k_d = initiator decomposition rate constant
k_t = termination rate constant

As the amount of polymer phase increases with conversion the rate deviates more and more from this equation due to a decrease in k_t. A full description of the models used to explain the deviations from ideality is given in [12], [13].

Medium Conversion (5 – 65 %). Polymerization continues in both the free monomer and polymer – monomer gel phases. This region shows the classical acceleration with increasing conversion [14]. Since termination occurs primarily by the diffusion together and collision of two bulky macroradicals, it is considerably slower in the viscous polymer phase. As a result the termination rate constant is dramatically reduced and the rate of polymerization in this phase is much faster. As the amount of polymer phase increases the rate of polymerization accelerates.

High Conversion (> 65 %). No free monomer is left to maintain the autogeneous pressure, which falls, and polymerization occurs in the polymer gel phase of rapidly increasing viscosity as the remaining VCM is consumed. Hence, the rate of polymerization increases still further to reach a maximum just after pressure drop but then decreases progressively due to increasing monomer starvation. When the instantaneous polymerization rate falls below the overall rate of reaction the batch is terminated, either by venting off unreacted VCM to the recovery plant or by adding a chain terminator and then venting. Depending on the properties required, a conversion of 70 – 95 % is chosen. It is uneconomic to continue to very high conversion, and as properties such as plasticizer absorption, dry up rate (i.e., the time taken to achieve a free-flowing PVC – plasticizer dry blend), and initial color – heat stability deteriorate rapidly above 85 – 90 % conversion, most flexible resins are stopped at around 85 % and rigid resins at around 90 % conversion.

4.1.4. Morphology

Control of the morphology of each PVC grain is the main parameter controlling the quality of a PVC resin. This subject covers mean grain size, grain size distribution, and, most important of all, porosity (cold plasticizer absorption) and bulk density, which are closely interrelated.

4.1.4.1. Control of Grain Size

At the beginning of the batch the bulk vinyl chloride phase is broken down into droplets of 30 – 40 μm mean size under the influence of agitation and by the presence of the water-soluble protective colloid, which is adsorbed at the monomer – water interface. As polymerization proceeds, graft copolymerization of PVC onto the interfacial layer of protective colloid reduces its mobility and protective ability, and droplet coalescence begins to occur at around 4 – 5 % conversion. As the conversion increases, changes in the surface layer of the droplet due to further polymerization suppress the droplet coalescence step, which ceases at 20 % conversion, and the grain size remains largely constant for the remainder of the polymerization. Altering the stirrer speed after this point has no further effect on the mean grain size (MGS) [15] of the final product, which is controlled to between 100 and 180 μm, depending on resin type, by a combination of initial agitator speed and protective colloid(s) concentration and type.

Polymerizations with high concentrations of colloid and less agitation give spherical grains of low porosity ($\leq$ 10 %) and very high bulk density ($\geq$ 700 g/L) and are of little interest, generally due to problems of VCM removal and poor gelation. Flexible resins are made with a low MGS (100 – 130 μm), rigid polymers higher (150 – 180 μm), and low K resins with intermediate size (130 –160 μm).

In extreme cases it is possible to stabilize the droplets to such a degree that no coalescence occurs. Specialized VCM – vinyl acetate copolymers for gramophone record production fall into this category as do blending resins (30 μm MGS) for use as viscosity depressants in plastisols (see Section 4.3).

As well as achieving the desired MGS it is equally important to control the size distribution. A Gaussean distribution is normally produced and it is important to make this as narrow as possible since a coarse fraction ($>$ 250 μm) can give rise to fisheyes (dispersion faults), and make VCM removal difficult as well as resulting in loss of yield due to screen rejects, while fines ($<$ 60 μm) can be lost in aqueous and gaseous effluent or cause powder flow problems.

4.1.4.2. Control of Porosity and Bulk Density

Porosity in PVC grains is created by a complex series of interrelated steps in the formation and growth of the submicroscopic structure within each droplet and also depends on the unique nature of the VCM – PVC system.

PVC is insoluble in its monomer, and the growing oligomers start to precipitate when the chain length exceeds 10 monomer limits [6]. This initial precipitation results in the formation of microdomains about 15 – 20 nm in diameter [16]. This occurs at as low as 0.001 % conversion [17]. The microdomains rapidly become unstable and aggregate to form domains (primary particle nuclei) of about 0.1 μm diameter. After this stage no further domains are formed and the number of primary particles is fixed. All new PVC radicals that are produced in the monomer phase collide with and are precipitated onto the vast existing surface area of primary particles before a new domain can be formed. Since the existing PVC phase is swollen with monomer and contains initiator, initiator radicals, and growing chains undergoing chain transfer, primary particles grow rapidly by accretion of new micro radicals and microdomains and by gel-phase polymerization. They in turn become unstable and a final agglomeration step to form 1 – 2 μm primary particle aggregates takes place. By the end of the polymerization the primary particles have grown to 1 μm within the aggregates, which themselves have grown to 2 – 5 μm. The whole mechanism is shown in diagrammatic form in Figure 5 and discussed in detail in [18].

The arrangement of the aggregates of primary particles within each monomer droplet has a major influence on the morphology of the final PVC grain. The conversion of VCM of density 0.85 g/cm^3 at 52 °C to PVC of 1.4 g/cm^3 produces a volume contraction of 39 %. If the polymerizing droplets contract totally the final grain has no porosity. If, however, the contraction is prevented totally the final grain porosity can be as high as 39 %. Therefore, the better the three-dimensional spatial arrangement of the aggregates relative to one another the higher the porosity that is achieved.

The main aim of the polymer technologist is to create the best possible spatial network of aggregates relative to one another so that a network is formed that is strong enough to resist droplet

Figure 5. Schematic representation of the mechanism of VCM polymerization (from [18], courtesy of Elsevier Applied Science Publishers)

contraction and hence maximize porosity. The sooner this is achieved in the polymerization the better the porosity attained. In practice 34 – 35 % is easily achievable. At ca. 65 – 70 % conversion all of the free monomer is consumed, and the only VCM remaining is that swelling the polymer gel (27 %) and in the vapor space and dissolved in the water. At this stage the voids in the grain (the porosity) are filled with batch water, so that the quantity of water in interstitial spaces between the grains is reduced and a significant increase in slurry viscosity is observed since less mobilizing water is available to separate the grains.

The control of bulk density or apparent density (AD) is more important than even porosity to the processor. The latter is concerned with charge size and cycle times in high speed mixers, output rates, motor torque and degree of gelation in extruders, and mechanical properties of the article being produced. These parameters are very dependent on AD. The reason for introducing the control of porosity before control of AD is that the latter is very heavily influenced by the former. Apparent density depends on porosity, grain shape, and grain size distribution in order of priority and is best described by examining the packing fraction (PF) concept, i.e., the ability of the somewhat irregular PVC grains to fill a space to the maximum efficiency.

$$\mathrm{PF} = \frac{(1 + 0.014 \cdot \mathrm{CPA})\,(\mathrm{AD} \cdot 0.1)}{1.4}$$

CPA = cold plasticizer absorption (porosity)
AD = apparent density

Figure 6. A) Classification of PVC grains; B) Typical cellular PVC grains – layout as in Figure 6 A
From [18], courtesy of Elsevier Applied Science Publishers

Most extruders used in processing PVC are of the twin screw type and these operate like a simple pump: increasing the feed rate by 10 % (10 % higher AD) increases the discharge or output rate by 8 – 9 % (see Chap. 8 in [14]). In practise, controlling porosity is relatively easy since a number of effective secondary stabilizers are available. Maximizing the AD is much more difficult since control of grain shape comes from a complex interaction of both agitation and choice of primary and secondary granulating agents together with in-house expertise of charging techniques and use of other additives. A range of grain shapes which can be produced is shown in Figure 6.

In practice typical property targets for porosity and AD are:

1) For flexible resins (K 70): porosity of ≥ 30 % and AD of ≥ 500 g/L
2) For rigid extrusion resins (K 66 – 68): porosity 20 % and AD 580 g/L
3) For bottle resins (K 57 – 60): porosity 18 – 20 % and AD 560 g/L

4.1.4.3. K-Value (Molecular Mass)

PVC is again rather unique in its relationship between reaction temperature and K-value. With PVC the rate of polymer formation by chain – chain termination is small due to the influence of gel phase polymerization described above. Instead, since chain transfer to monomer is a predominant step in the polymerization of VCM, the length of the polymer chain (degree of polymerization, DP) is determined by the ratio of the rate of chain propagation to chain transfer:

$$\mathrm{DP} = \frac{\text{Rate of propagation}}{\text{Rate of chain transfer}} = \frac{k_\mathrm{p}\,[\mathrm{R}^{\cdot}_n]\,[\mathrm{M}]}{k_\mathrm{tr}\,[\mathrm{R}^{\cdot}_n]\,[\mathrm{M}]} = \frac{k_\mathrm{p}}{k_\mathrm{tr}}$$

[M] = monomer concentration
$[\mathrm{R}\cdot_n]$ = radical concentration
k_p = propagation rate constant
k_tr = chain-transfer rate constant

As k_p and k_tr depend only on temperature the molecular mass of PVC is controlled by the reaction temperature (see Figure 7).

Figure 7. The effect of temperature on molecular mass and K-value

If a particularly low molecular mass polymer is required or if a reactor's pressure rating is too low to operate at very high temperatures an additional chain-transfer agent can be employed. This reduces the molecular mass by increasing the chain-transfer rate constant above that for monomer alone in the above equation. As a result DP decreases, depending on the quantity of chain transfer agent used.

The general K-value range of commercial resins is K 55 to K 75, with a few producers providing speciality resins outside this range to K 50 and K 80 and with just one or two K 90 – 100 polymers also being available. Despite the relatively narrow K-value/molecular mass range of most commercial resins (see Table 5) the polar nature of the PVC chain gives rise to a considerable melt viscosity span. Mechanical properties increase slightly with increasing K-value so wherever possible the highest K-value polymer is used. However, the power and mechanical ro-

bustness of equipment and the complicated melt flow pattern requirements in molds often restrict the K-value which can be used. For example, most bottles are made from K 57 polymers, some from K 60, but this is the limit for the application because bottles are blow molded so restricting the melt viscosity which can be handled.

4.1.4.4. Problem Areas

There are relatively few problems in the operation of the suspension polymerization process. However, to obtain the best possible quality and consistency some points need special attention.

In the past reactor fouling was bad and mechanical cleaning between each batch essential. With the advent of clean-wall technology, high-pressure rinse systems, and improved recipes it is now possible to operate in a closed manner, thereby reducing problems of VCM exposure (see Chap. 5 in [14]). Reactor opening for cleaning is reduced to once in several hundred batches. It is essential to ensure that the reactor is rendered completely free of polymer between batches since this is the most common cause of fisheyes. Equally important is to ensure there is no chance of cross-grade contamination in the downstream operations of slurry handling, stripping, drying, and storage. Contamination of the product by foreign substances is eliminated by good housekeeping and plant management together with the right choice of metals of construction and design. Stainless steel is widely used in many sections of PVC plants.

4.2. Bulk or Mass Polymerization of Vinyl Chloride

The mass polymerization process is virtually identical to that taking place within each monomer droplet in the suspension process. As such the mechanism and kinetics are very similar to those described in Section 4.1.3. The major difference is in the mechanical operation of the process.

About 10 % of world PVC production is provided by the mass process. The process was developed by Pechiney St. Gobain (PSG) who are now part of the French ATO Company. All mass producers are licensees of the PSG technology. The process is carried out in two stages:

1) In the first stage monomer and initiator are charged and vigorously agitated in a vertical, stainless-steel autoclave (prepolymerizer) of 8 – 25 m^3 capacity, fitted with a water- cooled jacket and condenser. Rapid polymerization takes place at 62 – 75 °C to give ca. 100 µm aggregated spherical flocs composed of 0.1 µm primary particles, which form the basis or seeds of the final PVC grain. Conversion is taken to 7 – 12 % in ca. 30 min, by which time the initiator used is exhausted.
2) The slurry from the prepolymerizer is discharged into the second-stage reactor, which has a volume of 12 – 50 m^3, with fresh initiator and more VCM. Up to five second-stages can be fed from one prepolymerizer. In the second stage the 0.1 µm primary particles making up each seed grow in size and fuse together to give the final grain of PVC of 130 – 160 µm diameter. As the conversion increases the physical nature changes from a wet powder at ca. 20 % to a dry one at 40 % conversion. The heat of polymerization is removed from the growing grains by evaporation of the VCM and condensation on the cooled wall of the reactor or in a water-cooled reflex condenser(s). The second stage takes 3 – 9 h, depending on K-value.

Originally, the second stage reactor was a horizontal jacketed vessel with one or more condensers, agitated by slowly rotating (6 – 10 rpm) ribbon blenders with some blades set very close to the reactor wall to keep it clean. However, it proved difficult to discharge and clean the reactor to a sufficiently high standard to prevent the formation of fisheyes (dispersion faults) in PVC grades intended for plasticized applications [19]. The product can contain up to 10 % of coarse material which must be sieved out and recovered by grinding, milling, and reclassifying.

This led to the development in 1978 of a vertical second-stage reactor of up to 50 m^3 capacity fitted with two independent agitators designed to overcome the above discharge problems. However, there has been little interest in this development and all recent investment in new PVC plants has been in the suspension process. In theory the mass process should be cheaper since it does not need a drying stage. However, it is a two-stage process, it is difficult to remove traces of unreacted monomer, and it gives a significant amount of oversized material, all of which offset its advantages.

Several of the smaller and older mass-polymerization plants have closed in recent years because they find it more and more difficult to meet increasingly stringent environmental standards and are becoming less and less competetive compared to suspension-polymerization plants on the basis of production rate.

The mass process is discussed in more detail in [19], [20].

4.3. Emulsion Polymerization of Vinyl Chloride

4.3.1. Introduction

The emulsion polymerization process involves the polymerization of monomer in an aqueous medium containing surfactant and a water-soluble initiator, producing PVC latices. PVC latices are colloidal dispersions of spherical particles, ranging in size between 0.1 and 3.0 µm. Most PVC latices are spray dried and then milled to obtain fine powders, made up of agglomerates of latex particles. When mixed with plasticizers they disperse readily to form stable suspensions. During mixing most of the agglomerates are broken down into the original latex particles. Such dispersion of fine particles in plasticizers are known as plastisols or pastes, and the powder is called dispersion or paste polymer.

The surfactant layer around the particle surface prevents their adsorbing the plasticizer at room temperature so they can be used as liquids and may then be spread on to fabric or other substrates, poured on molds, or deposited on formers to produce flooring, wall covering, artificial leather, balls, toys, or protective gloves. There are other grades of PVC polymers, produced by emulsion polymerization, that do not form plastisols and that are used as blends with suspension PVC grades for extrusion application or in the manufacture of battery separator plates. These so-called emulsion polymers are of only minor economic interest. Sales in latex form are very limited; latices are used in water-based paints, printing inks, and impregnated fabrics. The total production capacity of emulsion PVC is given in Table 6.

Table 6. World emulsion PVC production in 1989

Region	Production, 10^3 t	Percentage
Western Europe	662	41
United States	278	17
Japan	155	10
Rest of the world	513	32
Total capacity	1608	100

4.3.2. Emulsion Polymerization Processes

The ways to produce PVC latices are:

1) The classic emulsion polymerization, in which the particle size and particle size distribution are controlled by a water-soluble initiator and a surfactant [21–25]. They are monodisperse with a particle size typically less than 0.1 µm.
2) Seeded emulsion polymerization, in which the particle size distribution of the final latex depends on the amount and the size of the latex used as seed and on the amount of surfactant and the way in which it is added [26], [27]. A typical material has 0.2 and 1.2 µm particles (see Fig. 8).
3) Microsuspension polymerization, in which a monomer-soluble initiator is used. Polymerization takes place within the fine droplets in which the monomer is dispersed by passing a coarse emulsion of monomer, initiator, and surfactant through a mechanical homogenizer [28–30]. The resulting particle size distribution is Gaussian between 0.2 and 1.2 µm.
4) Polymerization of fine emulsions achieved by using a combination of a typical surfactant such as sodium dodecyl sulfate and a long-chain fatty alcohol. This gives rise to spontaneous emulsification of the monomer into very fine droplets. In this case the polymerization can be carried out by using a water-soluble or a monomer-soluble initiator [31]. The latex particle size distribution is the same as for microsuspension polymerization.

Figure 8. Electron micrograph of latex particles obtained by seeded emulsion polymerization

The industrial polymerization techniques used for carrying out these processes are the following:

1) Batch polymerization where all the monomer is charged at the beginning
2) Semibatch or semicontinuous polymerization, with the monomer added in stages or continuously as reaction proceeds
3) Continuous polymerization where monomer and other components are fed continuously into the reactor and the latex is withdrawn from the bottom of the reactor

These processes are used to achieve a wide range of latex characteristics, which are related to the rheological properties of the PVC plastisols [32].

4.3.3. Description of the Batch Process

The emulsion polymerization of PVC consists of the following stages:

1) Polymerization,
2) VCM removal,
3) latex storage,
4) drying,
5) milling,
6) packing and storage.

Figure 9 shows a schematic representation of the stages required for a plant which produces all the emulsion, seeded, and microsuspension grades.

Figure 9. Schematic representation of the stages required for a plant which produces all emulsion, seeded, and microsuspension grades

A recipe for a simple batch emulsion polymerization (in parts by weight) is as follows:

Demineralized water	110 – 140
Vinyl chloride	100
Emulsifier	0.1 – 1
Initiator	0.1 – 0.2

The polymerization takes place in an autoclave resistant to the VCM vapor pressure. Pressures of 6.4 – 10.0 bar correspond to polymerization temperatures of 40 – 60 °C, depending on the desired molecular mass. The polymerization reaction is strongly exothermic with a heat of polymerization of 1534 kJ/kg. Heat removal can be a problem as the size of the autoclave increases because the ratio between surface area and volume becomes less favorable. For this reason industrial plants commonly use water cooling, and external condensers. Modern plants use autoclaves with capacities ranging between 30 and 80 m^3. Large autoclaves can present agitation problems because low shear rates are required to maintain mechanical stability of the latex and to avoid coagulation.

Initiators. Although organic peroxides slightly soluble in water such as methyl ethyl ketone peroxide and 1-hydroperoxy-1′-hydroxydicyclohexyl peroxide can be used, the most widely used initiators are ammonium or potassium peroxosulfate. Their decomposition in aqueous solution is first order with respect to the peroxosulfate ion concentration [33]. The rate may be increased significantly by using a reducing agent. Redox catalysis involves the use of transition metal ions such as copper or iron [34]. The systems widely used in emulsion polymerization of vinyl chloride are potassium peroxosulfate – sodium bisulfate – copper or iron. Redox systems can also be used in microsuspension, an example being dilauroyl peroxide – copper – ascorbic acid [35].

Emulsifiers are very important in the emulsion polymerization of vinly chloride because they determine not only the latex characteristics but also the properties of the final product [36–38]. Moreover, the nature and the concentration of the emulsifier, together with the agitation, are major parameters controlling the mechanical stability of the latex during polymerization and handling, and the major cause of reactor wall encrustation and lump formation. Since the latex is dried by spray drying, the emulsifier remains in the resin and can influence properties of the product such as the flowability of the powder, plastisol formation, the viscosity of the plastisol, and also the properties of the final article such as heat stability, water adsorption, and coat adhesion. For this reason a wide variety of emulsifiers are used. During polymerization anionic types are usually used, while nonionics are generally added to the latex after polymeriza-

tion. Typical emulsifiers are the sodium salts of alkyl sulfates, alkyl sulfonates, alkylbenzenesulfonates, dialkyl sulfosuccinates, alkyl ethoxysulfates, fatty acid soaps, alkyl phenol ethoxylates, and fatty acid ethoxylates.

Particle Formation. Emulsifiers are characterized by the critical concentration at which their molecules aggregate to form micelles [39], [40]. In Figure 10 a plot of surface tension versus emulsifier concentration is shown; the point at which the curve exhibits a marked change is known as the critical micelle concentration (CMC). Conventional emulsion polymerization is carried out at a concentration above the CMC. In this way, particle formation is controlled by the micelles, which solubilize the monomer by swelling and become the loci of polymerization. The nucleation phase stops when the micelles disappear, and the emulsifier is absorbed on to the surface of the particles. Depending on the balance between the hydrophilic and hydrophobic part of the molecule, each emulsifier plays a specific role in the emulsion polymerization, as they have different CMC values, surface covering powers, and stabilizing effects.

Figure 10. Dependence of surface tension on emulsifier concentration

VCM Removal. The polymerization is terminated at 90 % conversion and is followed by the venting of unreacted monomer to a gas holder. After degassing, the latex contains 3 % vinyl chloride and further reductions must be made to fulfil legal requirements for environmental protection. The residual VCM is removed by stripping under vacuum in a stripping vessel. Although VCM loss from particles by diffusion is fast, VCM removal from an emulsion is much more difficult than from suspension slurries as the surfactants lead to large amounts of foam formation. Continuous processes using a thin-film evaporator or which spray the latex into an evacuated chamber against a countercurrent stream of gas reduce considerably the problems of foaming and coagulation [41–44]. The residual vinyl chloride monomer content of the latex after stripping ranges between 200 and 2000 ppm, depending on the type of latex and the operating conditions.

Drying and Milling. Although there are several different techniques to separate polymer from water, such as freeze drying, drum drying, or coagulation followed by centrifugation, the most widely used is spray drying because this confers a special structure to the dried particle that is important for the production of plastisols. A fine spray of latex is introduced into a hot air stream where evaporation takes place.

The spray is obtained by various types of atomizers, such as:

1) Spinning disks or wheels rotating at 15 000 – 20 000 rpm
2) Single pressure nozzles operating at 100 – 500 bar
3) Two-fluid pressure nozzles using compressed air up to 4 bar as atomizing fluid [45]

The drying air temperature at the inlet is 150 – 240 °C and at the outlet, 55 – 80 °C, depending on the quality of the required product and the type of latex. By varying the drying conditions it is possible to change the resin characteristics, and hence its use, even from a typical paste grade to a general-purpose emulsion resin, e.g., for rigid extrusion. The dry powder consists of spherical aggregates, with the size usually ranging from 1 to 100 µm diameter with an average of 30 – 40 µm. The aggregates are called secondary particles, to distinguish them from those of the latex, which are known as primary particles. The way the aggregates form is complex and depends on many parameters such as primary particle size, type and amount of emulsifier, mean residence time in the drying cham-

ber, droplet size of the spray, and temperature [46]. Figure 11 shows a scanning electron micrograph of spray-dried PVC particles formed from bimodal seeded latex.

Figure 11. Scanning electron micrograph of spray-dried PVC particles produced from bimodal seeded latex

Plastisol-grade resins, usually made from multimodal latex (i.e., with a Gaussian particle size distribution), are milled to reduce the size of the coarse fraction, which can cause problems in coating applications of the plastisol. Generally the viscosity of the plastisol increases when the polymer has been milled, so it is desirable to reduce milling as far as possible and to use air classification to remove the coarse fraction ($> 65\,\mu m$) under control. In industrial production, air classifiers or mills or a combination of both are used. After milling, the average particle size of the resin is in the range of $5-15\,\mu m$.

Polymers for rigid extrusion and for manufacturing plate separators in batteries are sold in unmilled form. Resins are characterized by analysis of molecular mass, emulsifier and salt content, pH of aqueous extract, granulometry, and viscosity and rheological behavior of the pastes.

4.3.4. Plastisols

Plastisols, commonly called pastes, are dispersions of PVC powders in plasticizers. A wide range of plasticizers are used in plastisol formulations, but the most widely used are C_4–C_{12} esters such as phthalates, adipates, azelates, sebacates, trimellitates, and phosphates. Chlorinated paraffins are used as secondary plasticizers. A good plasticizer should have low volatility, low color value, neutral reaction, resistance to hydrolysis, insolubility in water, flame resistance, and nontoxicity. As no plasticizer can satisfy all these properties several plasticizers are mixed to achieve the desired properties of the final product. Table 7 shows the influence of plasticizers on plastisol properties; Table 8, the influence of plasticizers on final product properties; and Table 9, the influence of resin characteristics on plastisol and final product properties.

Table 7. Influence of plasticizers on plastisol properties

Plastisol properties	Plasticizers *
Low fusion temperature	DBP, BBP, TCP
Low viscosity	DOA, DOS, DIPA
High viscosity	BBP, TCP, polymerics

The amount of plasticizer used in plastisol formulations plays a major role in determining the hardness and flexibility of the end product and can vary from 40 to 130 phr. In Figure 12 the influence of plasticizer content on plastisol viscosity is shown.

The other essential ingredients in plastisol formulations are:

1) Heat stabilizers, which generally are the same compounds used for suspension polymers.
2) Dyes and pigments suitable for coloring plastisols. The most widely used is titanium dioxide.
3) Fillers, generally inorganic materials such as calcium carbonate, barite, silicate, kaolin or china clay, are used primarily to lower costs and also to impart special properties such as hardness, abrasion resistance, and no sticking.
4) Blowing agents for foamed PVC production such as azodicarbonamide.
5) UV adsorbers to prevent the decomposition action of sunlight.
6) Esters of poly(ethylene glycol), phosphate esters, and fatty acid amines and amides are usually employed as antistatic agents.
7) Viscosity depressants, such as white spirit, poly(ethylene glycol) monolaurate, alkylphenols, low molecular mass paraffins.
8) Extender resin or filler polymer – a PVC grade of spherical form, made by the suspension process and therefore cheaper than dispersion resin, which is used to reduce cost and viscosity of the plastisol [47], [48].

In Table 10 the influence of plastisol ingredients on the final product characteristics is shown.

4.3.5. Polymer – Plasticizer Interaction

Figure 13 illustrates the types of dependence of viscosity on shear rate;

1) Newtonian (viscosity is independent of shear rate)
2) Pseudoplastic (viscosity decreases as shear rate increases)
3) Dilatant (viscosity increases with increasing shear rate)

Figure 13. Effect of shear rate on dilatant (a), Newtonian (b), and pseudoplastic (c) fluids

Figure 14. Effect of shear rate on the PVC plastisol viscosity (DOP/PVC = 100/50 at $T = 25\,°C$)

Over a wide range of shear rate a plastisol may exhibit all three types of behavior since the viscosity of plastisols rarely displays true Newtonian behavior. At low shear rates they are generally pseudoplastic, at intermediate values they show dilatancy, and may sometimes become pseudoplastic again at higher shear rates, as shown in Figure 14. There is no certainty on the exact mechanism as the rheology of PVC plastisols is complex and affected by many factors such as:

1) Polymer/plasticizer mixing ratio
2) Type of plasticizer and its interaction with polymer
3) Particle size and their distribution of primary particles
4) Structure, shape, porosity, and surface of the secondary particles
5) Surfactants, added during polymerization or in the paste
6) Molecular mass and molecular mass distribution
7) Paste-making conditions such as mixing temperature, time, and intensity [49].

4.3.6. Gelation and Fusion

Gelation is defined as the change from liquid to semisolid state, and fusion, when an homogeneous phase at molecular level between polymer and plasticizer is reached. These processes have been examined by determining viscosity changes of the liquid system, the tensile strength, and changes in complex viscosity and viscoelastic properties over the temperature range 25 – 200 °C.

At the beginning of heating, plasticizer viscosity decreases, as does the plastisol viscosity. At the same time, polymer particles adsorb plasticizer and swell, reducing the fraction of liquid plasticizer, and the viscosity then increases rapidly. When the liquid phase is completely absorbed by the particles, the system becomes dry. As the process continues the interparticle boundaries disappear and the polymer chains become increasingly entangled and development of the physical properties begins. At this point the gelation stage is complete and the fusion process starts, as illustrated in Figure 15. Further heating of plastisol makes the polymer flow into a continuous mass. The melt viscosity, after having reached a maximum, starts to decrease and the process passes through the fusion stage.

Morphology of the particles, particle size, particle size distribution and molecular mass of the resin affect the viscosity behavior. Low molecular mass resin starts the gelation phase earlier and completes the gelation process at lower temperature. The same result is obtained by using plasticizers with higher solvating action, while larger particle size increases gelation temperature or time because it slows the penetration of the plasticizer into the resin [50].

Figure 15. Changes in morphology and mechanical properties of PVC plastisol during gelation and fusion

4.3.7. Applications

Vinyl plastisols can be applied by spread coating, knife coating, roll coating, molding, dipping and spraying; the most widely used application is coating.

Coating. Vinyl plastisol can be used to coat paper, fabrics, metals, felt, and glass fibers to produce wallpapers, floor coverings, vinyl leather, conveyor belts, and tarpaulins. Each application needs its own formulation, in which the appropriate resin grade and plasticizer must be used to give the required rheological characteristics. In the case of fabric coating where direct spreading is employed, it is important to avoid penetration of plastisol into the fabric; therefore, the viscosity behavior of the paste must be strongly pseudoplastic at low shear rate and have moderate viscosity at high shear rate. In wallpapers, where thin coatings are applied, a low-viscosity resin with Newtonian behavior is required. In production of floor coverings, three or even four coatings are applied: an impregnation layer to saturate the fibers, one or two foam coats, and a wear layer with high mechanical strength. Each coat, which needs different grade resin to achieve the required properties, is gelled at 150 °C before application of the next layer. When the last coat is applied the entire coating is fused in an oven at 200 °C. The foam layer can be chemically or mechanically foamed [51]. Usually mechanical embossing is used to create surface textures and apply colored patterns.

Dipping. The product, mainly work, household, and surgical gloves, is obtained by dipping metal or ceramic molds or an article to be coated into the plastisol and then withdrawing it, draining it, and then curing it in an oven.

Molding is used for producing hollow articles such as balls, dolls, and toys. The process requires a plastisol with low viscosity at low shear rate that has a short gelation time and is easy to deaerate. In rotational molding the plastisol is poured into a cold mold that rotates around two perpendicular axes whilst entering an oven where it is heated with air to 200 – 250 °C. After gelation and fusion, the mold is cooled in a waterbath.

Further information is given in [32], [39], [40], [45], [48], [52–54].

4.4. Chlorinated Poly(Vinyl Chloride), CPVC

The softening point (heat distortion temperature or T_g) of PVC can be increased by chlorination of the polymer, either in a solvent or as a suspension. The normal chlorine content of 56.7 % is raised to 63 – 68 %, depending on type, and this increases the softening point from ca. 78 – 83 °C (depending on formulation) to at least 120 °C.

The older method involves chlorination of the PVC dissolved in a chlorinated solvent, but the process is expensive because of the need for an extensive solvent recovery system. However, it has the benefit of yielding a homogeneous material. The product is difficult to handle physically because of its very low bulk density.

The most common commercial process disperses the PVC grains in water and swells them with a chlorinated hydrocarbon. The reactor is

degassed to remove oxygen and heated to reaction temperature (50 – 60 °C); chlorine is added continuously and the system irradiated with UV light to produce chlorine radicals. Hydrogen chloride is produced as a byproduct and is removed at the end by washing with an inorganic base, after which the product is dried [55]. The degree of chlorination is variable, with the surface layers of the grains being preferentially treated.

CPVC is less thermally stable than conventional PVC and requires higher temperatures to develop good mechanical properties. Hence, it is difficult to process and quite expensive, but blends with suspension PVC can be used to achieve a specific softening point. CPVC products have not been very successful commercially but have found a specific niche in the market. They are used for hot-water systems in mobile homes in the United States and for the manufacture of fibers, for use in thermal underwear, in France.

5. Environmental Protection

Potential problem areas associated with the production, handling, and use of PVC are small if a few simple measures to avoid environmental contact and pollution are followed.

Losses of VCM from polymerization plants have been reduced to extremely low levels following conversion to closed-lid operation as a result of the toxicological problems discussed in Chapter 10 in [14]. Although modern column strippers reduce VCM levels in PVC to less than 10 ppm, a small quantity of VCM is lost from the drier section. The older batch strippers present more of a problem since they cannot achieve such low residual VCM contents.

PVC powder can be lost in centrifuge and scrubber effluent and by overfilling stock tanks and from pipeline leaks. It is important that all plant drains which are likely to contain PVC are directed to settling pits where flocculation treatment can be used so that the final discharge is free of PVC. All wet waste is collected and reclaimed as second- or third-grade material for use in noncritical applications such as one-trip horticultural products and fencing.

Powder losses from drier stacks can be minimized by ensuring that drier cyclones are adequately sized to the air conveying rates used. Some modern plants use bag filter systems to meet regulations that restrict the amount of PVC dust loss to 50 mg/m^3 air [56].

Compared to other polymers and typical metals PVC requires less energy per unit weight for its production [57]. Whilst plastics in general are blamed for long-lasting litter problems, it is significant that only 12 % of PVC is used for consumables, while 64 % is incorporated into products with an expected useful life of 15 years or more, probably much more. Disposal is therefore less of an immediate problem than is often thought.

As landfill sites are used up more municipal waste is being incinerated. Though inherently nonflammable, PVC will burn in an existing fire to release hydrogen chloride gas, which can be scrubbed out satisfactorily. Fears about the increased release of dioxins during incineration due to the presence of PVC in waste have proved to be unfounded [58].

6. Quality Specifications and Analysis

All PVC producers test a number of parameters on every batch produced as part of routine quality control operation. These include Kvalue, mean grain size and grain size distribution, apparent density, porosity, contamination, dispersion, color and heat stability, and residual VCM content. Most plants use statistical process control techniques to ensure that product consistency from batch to batch meets the stringent requirements of today's customers. It is difficult to give a typical testing regime since every plant makes batches of different size, has slurry blending facilities of differing degrees of sophistication, and has hoppers of different capacity on their drying plants. For a modern plant operating large autoclaves there is considerable testing of each polymerization batch (wet stage) together with additional testing of the dried and blended material as a cross check.

In-house tests have been collected and correlated by national and international standards organizations to make them universally applicable. ISO has defined tests and standards set up by other organisations such as the ASTM and DIN

so that ISO methods are now widely accepted worldwide. ASTM D 1755 defines a system for classifying general purpose (mass and suspension) and dispersion (paste) resins [59].

7. Storage and Transportation

Most plants handle more than 80 % of their production in bulk, and storage and supply in 25 kg bags is diminishing all the time as customers convert. After drying, the material is conveyed by blow-eggs (vessels in which the powder is pressurized and fluidized) of 2 – 15 t capacity via pipeline to the silo farm where it is stored in silos of capacity 100 – 500 t. PVC is discharged either directly or via a smaller loading hopper into 20 t road tankers, the most popular form of PVC transportation. Sometimes big-bags made of woven polypropylene are used for 1 t lots of PVC, and 20 t ISO metal containers are used for long distance deliveries. PVC is not a difficult material to handle and the logistics side of the operation is straightforward. It is essential to prevent cross-contamination of the PVC by other products and thorough inter-trip cleaning isessential, since many operators use their tankers for back carriage of a wide range of products, many nonpolymeric.

8. Processing and End Uses

Due to its unique combination of properties PVC is never handled on its own. Instead a complex formulation incorporating several additives is used. A typical base formulation contains: PVC resin, heat stabilizer(s), internal lubricant(s), external lubricant(s), processing aid, and additionally, impact modifier, filler(s), pigment, UV stabilizer, as well as primary and secondary plasticizers (for flexible applications; see → Plasticizers).

PVC is intrinsically unstable because of molecular defects in some of the polymer chains [60], [61] and when subjected to heat they initiate a self-accelerating dehydrochlorination reaction. Stabilizers neutralize the HCl produced and introduce nucleophilic substitution reactions that prevent further degradation [60], [61] (see also → Plastics, Additives, Chap. 4.).

The Ca – Zn stabilizer family is becoming increasingly popular as objections to the use of heavy-metal systems increases. In Europe withdrawal of cadmium stabilizers was planned for the end of 2001, and although it has been shown that use of the highly effective lead stabilizers is safe, adverse publicity will slowly erode their market position.

Table 11 gives a summary of the *heat stabilizers* in regular use.

Table 11. Heat stabilizers for PVC

Stabilizer	Properties
Lead stabilizers	
Lead soaps	Good heat stability
Lead salts	Sulfur staining
Liquid lead complex	Lead phosphites give good light stability
Lead one-pack systems	Kickers for chemical blown foam
Tin stabilizers	
Organo sulfur tin	Excellent heat stability, good clarity; poor light stability
Organo tin carboxylates	Medium heat stability
Excellent light stability	
Barium – zinc stabilizers	
Ba – Zn liquid	Good heat and light stability on high-quality grades; general-purpose stabilizers.
Calcium – zinc stabilizers	
Ca – Zn soaps	Low toxicity
Ca – Zn liquid	Medium heat and light stability
Organic co-stabilizers	
Thiourea derivatives	
Indol derivatives	
Amino crotonic acid esters	Synergistic effects with epoxy plasticizer and/or Ca – Zn, Ba – Zn
Diketones	
Organic phosphites	
Antioxidants	
Epoxidized soybean oil (ESBO)	Synergistic effect with Ca – Zn and Ba – Zn
Epoxy esters	

The polar, highly viscous PVC melt sticks easily to metal walls of extruder barrels, calenders, mills, etc. so an *external lubricant* is employed to assist the smooth passage of the melt. *Internal lubricants* help to reduce melt viscosity and prevent overheating and so help to ensure good color of the final product. *Processing aids* improve the surface appearance of extruded sections and reduce melt defects such as screw memory, where the helical nature of the screw

can be seen as regular ripples in the pipe surface. Many other additives can be used, e.g., *impact modifiers* for bottles and *UV stabilizers* and *fillers* (e.g., TiO_2) for house sidings and window frames to ensure the best possible in-service performance or longevity.

In all extrusion and some other conversion processes the PVC grain is not broken down to its constituent primary particles [62], unlike emulsion PVC processing (see Section 4.3.6). Instead the suspension grains (150 µm) gradually lose their original form by fusion and elongation under the influence of heat, pressure, and shear so that in badly processed PVC grain memory can be detected by optical microscopy of cross sections of extrudates [62]. In practise converters take great care to ensure that the degree of gelation (i.e., lack of grain memory) in the final PVC article is very high. Degree of gelation can be measured by determining the degree of attack by a poor solvent such as acetone or methylene chloride or by measurement of flow pressure to assess the strength and elasticity of partially fused material directly [63].

The enormous subject of processing, including different aspects such as formulations, types of processing equipment, gelation, rheology and mechanical properties is covered more widely in [62], [64–68].

Table 12. Typical end uses for PVC

Application	Rigid PVC	Flexible PVC
Construction	window frames, gutters, pipes, cars, housesiding, ports, roofing	waterproof membranes, cable insulation, roof lining, greenhouses
Domestic	curtain rails, drawer sides, laminates, audio and video tape cases, records	flooring, wallcoverings, shower curtains, leathercloth, hosepipes
Packaging	bottles, blister packs, transparent packs and punnets	cling film
Transport	car seat backs	underseal, roof linings, leathercloth upholstery, wiring insulation, window seals, decorative trim
Medical		oxygen tents, bags and tubing for blood transfusions, drips and dialysis liquids
Clothing	safety equipment	waterproofs for fishermen and emergency services, life-jackets, shoes, wellington boots, aprons and baby pants
Others	floppy-disk covers, credit cards	conveyor belts, inflatables, sports goods, toys

The versatility of PVC can be gauged by the very broad summary of typical end uses given in Table 12.

9. Economic Aspects

Fear of litigation, the need to handle VCM (a known carcinogen), and reduced funding have all but eliminated fundamental research into VCM polymerization. Work on processing of PVC continues, but at a much reduced level. Many companies have scaled down R & D and process development, and raw materials suppliers are now increasingly responsible for technological developments.

Since 1992 the main trend in the PVC industry has been survival by amalgamation. Some well-known companies, including pioneers from the 1940s (e.g., B. F Goodrich/GEON, ICI, and Chisso) have disappeared through aquisition, and many others have formed larger conglomerates to survive. The current feeling in the industry is that a minimum capacity of 500 000 t/a is required for a viable operation.

Irresponsible investment in new plant near the peak of the economic cycle has resulted in over-capacity, weakened prices, lower company profits, and ecomomic caualties, just as it did ca. 1990. Even the staid Japanese PVC industry has seen amalgamations and plant closures since ca. 1995, and the former 15 companies have been reduced to just five major production groups. Changes in the Western European PVC scene are summarized in Figure 16.

Table 13 lists the regional capacities (in 10^3 t/a) of the top ten producers, which represent 48 % of world capacity of 29.8×10^6 t/a. World production in 2000 was 23.3×10^6 t (78 % of capacity).

Since ca. 1990 China has emerged as a major force on the global PVC market, and its tremendous import capacity has had a large impact on the world price/consumption relationship. The eight main Chinese producers use ethylene-based VCM and produce 42 % of total output, while about 70 % of producers manufacture the remaining 42 % using VCM from a calcium carbide based process. Between 1996 and 2000 output of PVC increased on average by 12 % per annum, consumption by 15 %, and imports by 20% per annum.

Table 13. Regional capacities (in 10^3 t/a) of the top ten PVC producers in 2000

Company	S. America	Asia	NAFTA	W. Europe	Total
Shin-Etsu	140	550	1500	520	2710
Formosa		1240	1170		2410
Oxy-Vinyls			2020		2020
Solvay	450	190		1250	1890
EVC				1320	1320
Georgia-Gulf			1270		1270
Atofina				890	890
Borden			690		690
L.G. Chemical		600			600
Taiyo Vinyl		600			600

The top 10 producers represent about 48 % of world capacity of 29.8 million tonnes. World production in 2000 was 23.3 million tonnes (78 % occupacity).

In China

8 main producers use ethylene based VCM production process and produce 58 % of total output.
70 % of production enterprises use VCM from a calcium carbide based process and produce 42 %.
PVC Production Plants:

Consumption of PVC Resin	Number of Plants
> 100 ktpa	8
> 50 ktpa	10
< 50 ktpa	51

Between 1996 and 2000
Domestic output of PVC increased 12 % in yearly average.
Domestic consumption increased 15 % in yearly average.
Imported quantities of PVC increased to 20 % in yearly average.
Consumption per capita

West Germany	27.1
North America	15.1
Western Europe	14.6
South America	3.6
East Europe	3.5
China	3.1
Asia/Pacific	2.6
Africa/Middle East	1.9
India	1.0

Table 14. World supply/demand balance for PVC in 1999 (in 10^3 t/a)

	Capacity	Operating rate, %	Production	Imports	Exports	Consumption
N. America	7480	91	6800	110	370	6540
S. America	1930	81	1560	470	460	1570
W. Europe	6100	89	5410	610	390	5630
Japan	2810	87	2450	10	780	1680
Korea	1150	100	1150	30	380	820
Taiwan	1760	79	1390	160	360	1190
Other Asia	4620	74	3430	1950	450	4930
E. Europe	2290	54	1240	250	760	730
Africa	360	85	310	210	10	510
Middle East	910	88	810	510	340	980
Others	3820	67	2550	1050	1120	2480

Figure 16. Evolution of the PVC industry in Western Europe
j.v. = joint venture

World PVC production was 23.3×10^6 t/a in 2000, and growth ranged from −3 (Japan) to +8 % (China). Overall long-term growth worldwide is estimated at ca. 4 %. Table 14 summarizes the world supply/demand balance.

10. Toxicology and Occupational Health

Vinyl Chloride Monomer (VCM). Since vinyl chloride boils at − 13 °C it is handled as a compressed liquid. It has a vapor density greater than air so precautions are taken in design not to contain the vapor in restricted areas. Protection of reactors by relief valves or bursting disks and double-valve isolation of all lines containing VCM are basic precautions taken in the design and construction of any PVC plant vessel which contains monomer. The gas is explosive between 3.6 and 25 vol % with air and 12 vol % oxygen is required for ignition [69]. Therefore, a special series of working conditions must be satisfied in the working environment and great care is always taken to purge lines, pumps, valves, etc. before any maintenance work is started. Thorough documentation (e.g., clearance to work certificates) are always used to ensure proper isolation of plant equipment is carried out before any entry. The whole plant is contained within a "red-fence" area where smoking is not permitted and where all electrical equipment is of a gas-tight and "flame-free" construction.

VCM has a narcotic effect at 8 – 12 vol % concentration and can cause death at higher concentrations [69]. For this reason early VCM and PVC plants were designed to avoid build-up of gas above 1000 ppm in the atomosphere. VCM has a pleasant ethereal smell which is first noticed at concentrations of 500 – 2000 ppm.

Exposure to VCM has been shown to lead to two distinct problems. In the mid-1960s it became clear that a number of workers involved in reactor cleaning suffered from a bone con-

dition called acroosteolysis (AOL), which affects mainly the hands and feet. Removal of the worker from exposure to VCM leads to an almost complete recovery. Since improvements to ventilating reactors and the introduction of high-pressure water cleaning the incidence of AOL has ceased [70]. A study of long-term exposure of rats to 30 000 ppm VCM did not reproduce any sign of AOL but they did develop cancers in various sites [71].

Subsequently, an extensive study with a wide range of dose conditions relating to occupational exposure was begun in 1971 at the Institute of Oncology in Bologna [72]. This showed that a very rare liver cancer, angiosarcoma could be formed in rats at levels of 250 – 500 ppm VCM. The first correlation between exposure to VCM and cancer in humans was made in 1973 when three workers at a plant in Louisville, Kentucky were shown to have died from angiosarcoma [73]. Since then other cases have been identified, all of which involved workers exposed to high concentrations of VCM as reactor cleaners or charging operators. As the period between first exposure to VCM and the appearance of angiosarcoma is 20 to 25 years it is likely that the incidence of the disease will soon decrease following improvements made to operation of PVC plants since 1973.

The knowledge that VCM is a human carcinogen has led to the introduction of very stringent controls by governmental and regulatory authorities to limit the exposure of workers and the general public to the monomer. In the United States, OSHA has set an 8-h TWA of 1 ppm VCM. During a shift an employee's exposure must not exceed 5 ppm over a period of 15 min or less [74]. The European regulations, EC directive 78/610, require an annual average of < 3 ppm in the plant's airspace with alarm values of 15 ppm over 1 h, 20 ppm over 20 min, and 30 ppm over 2 min.

Poly(Vinyl Chloride). Strict limits have been set for the quantity of residual VCM in processed PVC articles intended for use in food contact applications.

In 1979 the EC set an upper limit of 1.0 ppm in the article and 10 ppb in the food. In 1986 the FDA suggested levels of ≤ 5 ppb in rigid and ≤ 10 ppb in plasticized PVC articles in food contact applications. To ensure these limits are met, PVC producers aim for these concentrations in the polymer grains themselves so that any further loss during processing ensures even greater safety.

There is little evidence that PVC powder itself causes any significant medical problems but steps are always taken to reduce powder emissions because of its nuisance value.

Polyvinyl Compounds, Others

General aspects of polymers, properties and testing, processing, additives, and analysis are discussed in Plastics, General Survey; Plastics, Properties and Testing; Plastics, Processing; Plastics, Additives; and Plastics, Analysis, respectively. States of order are treated in Plastics, Properties and Testing. Fundamental aspects of polymerization reactions are treated in Polymerization Processes.

1. Poly(Vinyl Alcohol)

In 1924, W. O. Herrmann and W. Haehnel [1] were the first to prepare poly(vinyl alcohol) by saponifying poly(vinyl esters) with stoichiometric amounts of caustic soda solution. At about the same time, work was resumed in the Hoechst Works of the IG Farbenindustrie on the saponification of poly(vinyl ester) derivatives such as poly(vinyl chloroacetate), which F. Klatte and E. Zacharias had begun in 1912 in the Chemische Fabrik Griesheim Elektron.

In 1932, W. O. Herrmann, W. Haehnel, and H. Berg [2] discovered that poly(vinyl alcohol) can be prepared from poly(vinyl esters) by transesterification with absolute alcohols in the presence of catalytic amounts of alkali. The transesterification principle is still used by all poly(vinyl alcohol) producers. Work on the conversion of poly(vinyl acetate) to poly(vinyl alcohol) contributed substantially to the proof of Staudinger's theory of the structure of macromolecules [3].

In the transesterification of poly(vinyl acetate) to poly(vinyl alcohol), products with different acetyl group contents can be obtained depending on production conditions. The range of commercial poly(vinyl alcohols) extends from fully saponified types to products with degrees of hydrolysis of ca. 70 mol %.

In addition to these poly(vinyl alcohols), which dominate the market, saponification products of vinyl acetate – ethylene copolymers are also commercially important [4]. Numerous saponification products of other vinyl acetate copolymers (e.g., with other vinyl esters, longer-chain α-olefins, vinyl ethers, vinyl halides, acrylate and methacrylate esters, and unsaturated acids, nitriles, and amides) are described in [5].

1.1. Structure and Crystallinity

Poly(vinyl alcohol) contains mainly 1,3-diol units. The content of 1,2-diol units in poly(vinyl alcohols) obtained by hydrolysis of poly(vinyl acetates) is $<1-2\,\%$. The content of 1,2-diol sequences can be reduced by lowering the polymerization temperature of vinyl acetate [6] or using other vinyl esters such as vinyl formate [7] or vinyl benzoate [8]. The content of 1,2-diol units influences some properties of poly(vinyl alcohols) (e.g., the degree of swelling of films in water [9]).

Carboxyl and carbonyl end groups are more abundant than initiator end groups in poly(vinyl alcohols) [10]. Poly(vinyl alcohol) is slightly branched as a result of chain transfer reactions occurring during the polymerization of vinyl acetate [11]; → Poly(Vinyl Esters).

In partially saponified poly(vinyl alcohols) the acetyl groups can be distributed statistically or blockwise, depending on production conditions. The nature of the acetyl group distribution influences important properties of poly(vinyl alcohols), such as melting point [11], surface tension of aqueous solutions [12], and emulsifying and protective-colloid properties [13].

The stereochemistry of poly(vinyl alcohols) is fixed during the polymerization of vinyl monomers. It is determined from the position and intensity in the ^{1}H NMR spectrum of the hydroxyl proton signal, which consists of three doublets assigned to syndiotactic (S), atactic (A), and isotactic (I) triads of poly(vinyl alcohol) [14, 15]. According to this, poly(vinyl alcohol) obtained by radical polymerization of vinyl acetate followed by hydrolysis is predominantly atactic in structure (24 % I, 44 % A, 32 % S). Stereochemically more uniform poly(vinyl alcohols) are obtained when the initial polymer is poly(vinyl trifluoroacetate) (23 % I, 36 % A, 40 % S) or poly(vinyl *tert*-butyl ether) (55 % I, 32 % A, 13 % S). Poly(vinyl alcohols) of different tacticity have different properties. For example, on acetalization (see Chap. 2), the isotactic sequences react first, and the highest stability toward water is shown by syndiotactic poly(vinyl alcohols) [16].

Poly(vinyl alcohol) is a crystalline polymer (for X-ray structure, see [17]). The degree of crystallinity depends strongly on the structure and previous history of the poly(vinyl alcohol). Acetyl groups and other incorporated groups of any kind lower the crystallizability [18]. The degree of crystallinity of fully saponified poly(vinyl alcohols) is increased by heat treatment, which also lowers their solubility in water [19]. This effect is less marked for poly(vinyl alcohols) that contain acetyl groups.

1.2. Production

Since the monomer of poly(vinyl alcohol), vinyl alcohol, is nonexistent – the tautomeric equilibrium lies on the acetaldehyde side – only indirect methods are available for the production of poly(vinyl alcohol).

Attempts to prepare poly(vinyl alcohol) by polyaldol condensation of acetaldehyde have had little success up to now [20]. Polymerization of the metal vinyl compounds (which are relatively complicated to prepare), followed by saponification, leads in general to poly(vinyl alcohols) of low molecular mass [21, 22].

The most important manufacturing process for poly(vinyl alcohol), which is used worldwide, is the polymerization of vinyl esters or ethers, with subsequent saponification or transesterification. The preferred starting material is vinyl acetate, but derivatives of vinyl acetate (such as vinyl mono- and dichloroacetate, vinyl bromoacetate [23], and vinyl trifluoroacetate [24]), vinyl esters of other carboxylic acids (such as vinyl formate [25], vinyl butyrate [26], and vinyl benzoate [27]) and vinyl ethers (such as benzyl vinyl ether [28]) can also be used. The hydrolysis of poly(vinyl acetate) is easily controllable, and no side reactions occur.

Production Conditions. Since the properties of poly(vinyl alcohols) depend primarily on their molecular mass and residual content of acetyl groups, industrial production processes are optimized for precise control of these two characteristics.

The preferred process for the production of poly(vinyl acetate) for further processing to poly(vinyl alcohol) is polymerization in methanol.

Factors determining the molecular mass of poly(vinyl acetate) and, accordingly, of poly(vinyl alcohol) are the polymerization temperature, vinyl acetate – methanol ratio, and polymerization conversion [29]. Lowering the polymerization temperature, the proportion of methanol, and the conversion increases molecular mass.

In general, poly(vinyl acetate) should be as free as possible of monomeric vinyl acetate because the latter is cosaponified. Any acetaldehyde formed colors the poly(vinyl alcohol) yellow in alkaline saponification as a result of aldehyde resin formation and acetalizes it in acid saponification.

Conversion of poly(vinyl acetate) to poly(vinyl alcohol) can be carried out in solution, suspension, or emulsion with alkaline or acidic catalysts. The preferred process is transesterification in methanol in the presence of catalytic amounts of sodium methoxide, with formation of poly(vinyl alcohol) and methyl acetate.

Hydrolysis conditions influence the structure of the poly(vinyl alcohol) formed. By varying catalyst concentration, reaction temperature, and the reaction time, the content of residual acetyl groups can be adjusted practically at will. The nature of the distribution of the remaining acetyl groups in partially saponified poly(vinyl alcohol) is determined by the choice of catalyst and by the solvent. Thus, in alkaline saponification the residual acetyl groups are distributed largely blockwise [30], and in acidic saponification largely statistically [31].

Figure 1. Belt saponification process for poly(vinyl alcohol) [38,39]
a) Mixing vessel; b) Cover plate; c) Discharge; d) Conveyor belt; e) Mill; f) Washing vessel

If methyl acetate [31,32] or benzene [18] is added to methanol in transesterification, poly(vinyl alcohols) with increased block formation by the remaining acetyl groups are obtained. In aqueous solution with acid catalysis, equilibrium conditions occur. The degree of saponification can be adjusted by the addition of different amounts of acetic acid [33]. Partly acetylated poly(vinyl alcohols) prepared by reacetylation of fully saponified products in homogeneous aqueous systems have a completely statistical distribution of the acetyl groups [31].

Poly(vinyl alcohol) is manufactured in both batch and continuous processes. For the continuous polymerization of vinyl acetate in methanol, high molecular masses can be achieved only with relatively low methanol content and low vinyl acetate conversion [34]. Part of the vinyl acetate must therefore be recycled.

In the alkaline hydrolysis of poly(vinyl acetate) in methanol, a highly swollen gel is formed initially. Then, toward the end of saponification this swollen gel contracts and releases solvent (syneresis), becoming a tough gel of poly(vinyl alcohol).

An example of a continuous process is the belt saponification of Shawinigan Chemicals (Fig. 1) [35,36].

Suspension- or solution-polymerized poly(vinyl acetate) is mixed with methanolic alkali in a mixing vessel to give a 30 % methanolic solution, which is fed to a conveyor belt, where it remains until syneresis begins. The gel is ground in a mill, neutralized with acid, washed with methanol, separated from the mother liquor, and dried. The mother liquor, consisting of excess acid, methanol, and methyl acetate, is worked up in further process stages.

Saponification in a kneader is an example of a discontinuous process (Fig. 2) [37,38]. Poly(vinyl acetate) is dissolved in methanol in a kneader, and the amount of sodium methylate in methanol required for the desired degree of saponification is added. The transesterification process at 20 – 30 °C usually lasts about 8 h. Then the mixture of methanol and methyl acetate is driven from the kneader at 60 – 70 °C with a nitrogen stream, and poly(vinyl alcohol) is fed to subsequent processing stages.

Figure 2. Manufacture of poly(vinyl alcohol) in a kneader [37,40]
a) Kneader; b) Dust separator; c) Trap; d) Cooler; e) Blower; f) Heater; g) Mill; h) Sieve.

Subsequent process stages [39,40] include separation of vinyl acetate from partly reacted solution polymers in stripping columns, separation of the saponification mother liquor into methyl acetate and methanol, hydrolytic cleavage of methyl acetate with subsequent distillation of methanol and acetic acid, and drying of poly(vinyl alcohol), which can be carried out batchwise or continuously.

Trade Names. Poly(vinyl alcohol) is supplied by manufacturers under different trade names: Mowiol (Hoechst, Germany), Polyviol (Wacker Chemie, Germany), Rhodoviol (Rhône-Poulenc, France), Alcotex (Revertex, England), Polivinol (Rhodiatoce, Italy), Denka Poval (Denki Kagaku Kogyo, Japan), Gohsenol (Nippon Gohsei, Japan), Kurashiki Poval (Kuraray, Japan), Shinetsu Poval (Shinetsu Chem. Ind., Japan), Unitika Poval (Unitika, Japan), Elvanol (Du Pont, US), Gelvatol (Shawinigan Resins, US), Lemol (Borden, US).

Storage and transport of poly(vinyl alcohol) require no special precautions: the polymers must merely be protected from the effects of moisture and heat.

Wastewater Problems. Poly(vinyl alcohol) is degradable in sewage treatment plants with an adapted biological clarification stage. However, when discharged into receiving waters it is degraded only with difficulty, as shown by the 5-d BOD values. Tests showed that fish (guppies) are not harmed, even at a poly(vinyl alcohol) concentration of 500 mg/L of water [41].

1.3. Properties

Physical Properties. Normal commercial poly(vinyl alcohols) are white to yellowish and are supplied as powder and granules. The main factors influencing physical properties are the degrees of polymerization and hydrolysis. Most commercial products fall into two main groups: those with a degree of hydrolysis of about 98 mol % of the acetyl groups, and those with a degree of hydrolysis of 87 – 89 mol %. Both groups include products with degrees of polymerization from ca. 500 to 2500. Data such as the viscosity of the aqueous poly(vinyl alcohol) solutions, the molecular mass of the precursor poly(vinyl acetates), and the degree of hydrolysis or ester number are frequently used by manufacturers of poly(vinyl alcohol) to characterize their products.

The melting point and glass transition temperature depend not only on the content and distribution of acetyl groups but also on the tacticity and water content. For fully saponified poly(vinyl alcohols) a melting point of 228 °C and a glass transition temperature of 85 °C are reported [42]. Prolonged heating of dry poly(vinyl alcohol) above 110 °C can lead to evolution of gaseous cleavage products.

Poly(vinyl alcohol) Solutions. Water is the most important solvent for poly(vinyl alcohol). Certain polar solvents such as diethylenetriamine [43], dimethyl sulfoxide [44], formamide, dimethylformamide, and hexamethylphosphoric triamide [45] are relatively good solvents. The rate of dissolution in water increases with decreasing degree of polymerization and degree of hydrolysis. The degree of polymerization has a greater effect with fully saponified than with partially saponified poly(vinyl alcohols). Poly(vinyl alcohols) with degree of hydrolysis below 88 % dissolve better in water at low than at elevated temperature [46].

Poly(vinyl alcohol) solutions are obtained by stirring poly(vinyl alcohol) into water at ca. 90 °C. Industrially they are produced in indirectly heated dissolving tanks or by introducing steam into poly(vinyl alcohol) suspensions. For prolonged storage, solutions must be stabilized against microbial attack by adding preservatives.

The viscosity of aqueous solutions depends on the degrees of polymerization and hydrolysis of poly(vinyl alcohols) as well as on the concentration and temperature. Fully saponified poly(vinyl alcohols) yield more viscous solutions than partially saponified poly(vinyl alcohols) at the same degree of polymerization [46]. Concentrated solutions of highly saponified poly(vinyl alcohols) undergo a viscosity increase on prolonged standing, which can be reversed by heating.

Many inorganic salts, especially sulfates and phosphates, precipitate poly(vinyl alcohols) from aqueous solution [42]. Boric acid and borax act as thickeners [47]. The conductivity of aqueous poly(vinyl alcohol) solutions depends on their electrolyte content, which is carried over

from the precipitation process: for 10 % solutions it is ca. 0.1 – 0.7 mS/cm [48].

Chemical Properties. Poly(vinyl alcohol) undergoes the chemical reactions expected of a polyglycol with secondary hydroxyl groups. The most important are the formation of esters, ethers, and acetals [42,49,50]. Only a few typical reactions are mentioned here. Examples of inorganic esters are poly(vinyl nitrates), phosphates, and sulfates. Organic esters can be obtained by reaction with acid anhydrides or acid chlorides. The cinnamate esters are important for the production of light-sensitive polymers [51]. Many poly(vinyl alcohol) ethers have been described. The products of the reaction of poly(vinyl alcohol) with ethylene oxide are suitable for the production of films with good solubility in cold water. Of the reaction products of poly(vinyl alcohol) and aldehydes, poly(vinyl butyrals) have attained importance as raw materials in the manufacture of safety glass.

1.4. Uses, Toxicology, and Economic Aspects

Protective Colloid in Emulsion and Suspension Polymerization. Poly(vinyl alcohol) has proved outstandingly effective as a protective colloid for the production of plastic dispersions, especially of poly(vinyl acetate) homo- and copolymers, and as a suspension stabilizer. By selection of suitable types and combination with emulsifiers, dispersions with extremely varied properties can be produced, most of which are used in adhesives [31,52–55].

Adhesives. Poly(vinyl alcohol) is used in aqueous solution, alone or in combination with plastic dispersions, for packaging adhesives, cigarette adhesives, and moistenable gumming [56].

Sizes. The most important field of application in the textile industry is the sizing sector. Poly(vinyl alcohol) is an excellent raw material for the sizing of stable fiber yarns and filaments [56–59].

Paper Industry. Applications in the paper industry are surface sizing and the production of coated papers and special papers with specific barrier properties. Poly(vinyl alcohol) has excellent pigment binding power and is a good carrier for optical brighteners [60–63].

Other Uses. Poly(vinyl alcohol) is used for bonding nonwoven fabrics of all kinds, especially glass fiber; in temporary bonding agents for special ceramics; in secondary brighteners in electroplating and electroforming; for the production of protective lacquers and decorator sizing and solvent-resistant dipped products, such as gloves and aprons; for the modification of surface coating formulations; as a release agent for cast resin moldings; in the production of photoresists for the printing industry and of highly absorbent sponges; and in binders and thickeners for cosmetics.

Poly(vinyl alcohol) is also very suitable for the thermoplastic production of packaging films with graded water solubility. Good plasticizers for poly(vinyl alcohol) are ethylene glycol, glycerol, trimethylolpropane, neopentyl glycol, poly(ethylene glycols) with molecular masses up to ca. 400, and ethoxylated phosphate esters. Films of plasticized poly(vinyl alcohols) are practically impermeable to nitrogen, oxygen, and carbon dioxide [64]. Saponification products of vinyl acetate copolymers (e.g., with ethylene or long-chain α-olefins) are also used in the film sector [60,64].

Toxicology. In testing poly(vinyl alcohol) for toxicity and for compatibility with skin and mucous membranes, no negative effects were found in animals (LD_{50}; 90-d feeding test on rats; FDA patch test; dermal application) [48].

Economic Aspects. The worldwide production capacities (in 10^3 t/a) are as follows:

World	650
Japan	239
United States	127
Western Europe	60

2. Poly(Vinyl Acetals)

The first poly(vinyl acetal) was obtained by W. Haehnel and W. O. Herrmann in 1924 by

the reaction of poly(vinyl alcohol) with benzaldehyde in concentrated hydrochloric acid [65]. In the following years, more methods were developed, in which the reactions were carried out in concentrated acids and anhydrous solvents. In 1929, H. Hopf and E. Kühn succeeded in acetalizing aqueous poly(vinyl alcohol) solutions in the presence of dilute acid [66]. Shortly afterward G. Kränzlein et al. reacted poly(vinyl acetate) with aldehydes with simultaneous saponification and acetalization to give poly(vinyl acetals) [67].

2.1. General Aspects

Since most aldehydes and many ketones react with vinyl alcohol homo- and copolymers, a number of poly(vinyl acetals) can be obtained. However, at present, only poly(vinyl butyral) and poly(vinyl formal) are commercially important. All other poly(vinyl acetals) have until now been used only in isolated cases in specialty applications.

The main reason for the limited use of poly(vinyl acetals) is that their manufacture, which requires several stages, is expensive in comparison with other plastics. Their use is restricted also by their sensitivity to acids and oxidation. However, they have excellent mechanical and adhesive properties, and good processibility.

Production and Properties. The intermediate for all poly(vinyl acetal) syntheses is poly(vinyl alcohol). In principle, the way in which poly(vinyl alcohol) is produced, is immaterial. The only industrially important method is radical polymerization of vinyl acetate. Poly(vinyl acetate) is then saponified with catalysis by alkali to poly(vinyl alcohol), which is acetalized in the presence of mineral acids (two-stage process). Poly(vinyl acetate) can also be saponified in acid, and the saponification combined with acetalization, in a one-process operation (single-stage process).

Important properties of poly(vinyl acetals), above all the molecular mass and molecular mass distribution, are fixed during polymerization of vinyl acetate. A good starting material for acetalization is poly(vinyl acetate) with a narrow molecular mass distribution, such as is obtained by solution polymerization of vinyl acetate with incomplete conversion.

The poly(vinyl alcohols) used to produce poly(vinyl acetals) always contain unsaponified vinyl acetate units (generally 1 – 8 wt %). This figure is usually unchanged by acetalization in the two-stage process. Poly(vinyl acetals) produced in the single-stage process often have considerably higher acetate content since the acid saponification of the acetate groups is relatively slow.

Poly(vinyl acetals) also differ in the degree of acetalization, which can vary within wide limits and strongly influences the polymer properties, especially strength, solubility, and adhesiveness. According to Flory [68], for statistical reasons, no more than 81.6 % of the alcohol groups in poly(vinyl alcohol) can react with aldehydes. The acetalization reaction is assumed to be exclusively intramolecular (i.e., it proceeds without cross-linking). In fact, only in the reaction of poly(vinyl alcohol) with formaldehyde can cross-linking be produced relatively easily, although even in this case, intramolecular acetalization is preferred. In the reaction with higher aldehydes, intermolecular acetalization is much more difficult or impossible [69].

Thus poly(vinyl acetals) are terpolymers of the formula

where x, y, and z can vary over wide ranges, and the alcohol, acetal, and acetate groups are generally distributed statistically. Although indications are that poly(vinyl acetals) with block structures can be prepared, little is known about such structures.

In the reaction of formaldehyde with poly(vinyl alcohol), isotactic vinyl alcohol units, which give *cis* rings on acetalization, react more readily than syndiotactic vinyl alcohol units, which give more highly strained *trans* rings [70]. Therefore, in the acetalization of poly(vinyl alcohol), the isotactic vinyl alcohol units react first while the syndiotactic units remain. Individual acetalization processes appear to differ, however, so poly(vinyl butyrals) of the same

empirical composition can vary not only in the blocklike or statistical arrangement of their repeating units but also in the tacticity of the residual vinyl alcohol sequences. The properties of poly(vinyl acetals) are affected as a result. For example, syndiotactic vinyl alcohol polymers exhibit pronounced intermolecular hydrogen bonding, which is the reason for their high strength and poor solubility.

Stabilization. Like all acetals, poly(vinyl acetals) are sensitive to acid hydrolysis. If oxygen is also present, peroxidic oxidation products of the aldehyde that splits off can cause cleavage of the molecular chain and increase the acidity of the polymer so that the decomposition accelerates autocatalytically.

Poly(vinyl acetals) can be stabilized effectively by addition of alkali [71]. However, poly(vinyl acetals) are also sensitive to oxidation in neutral or alkaline medium. Therefore, stabilization with antioxidants, in addition to alkali, is advisable. Of the numerous antioxidants proposed [72], phenols have proved effective [73], whereas phosphites [74] or triazole derivatives [75] are effective as costabilizers.

Unprocessed poly(vinyl butyral) powders cannot be stored indefinitely, even in the stabilized state. Manufacturers therefore recommend a maximum storage period of 6 – 12 months.

Raw Materials. The only significant raw materials are poly(vinyl acetate) or poly(vinyl alcohol) and formaldehyde or *n*-butyraldehyde. The polymer starting materials should be as pure and colorless as possible. Commercial products can generally be used without further purification.

The poly(vinyl alcohol) must not contain insoluble components. The aqueous poly(vinyl alcohol) solution must therefore be filtered before acetalization. Although technical-grade formaldehyde can be used directly for acetalization, butyraldehyde should be purified by distillation and stored under nitrogen. It must not contain more than 2 % impurities, especially other aldehydes and acids. The inorganic acids used for acetalization should be free of heavy metals.

2.2. Poly(Vinyl Formal)

The importance of poly(vinyl formal) is limited. Its production probably makes up only 10 % of total poly(vinyl acetal) production, if the acetalized fibers produced from poly(vinyl alcohol) are not considered.

Production. Since the commercially important poly(vinyl formals) contain a relatively large number of vinyl acetate units, a single-stage process for manufacturing directly from poly(vinyl acetate) is particularly suitable.

In the processes developed in the United States [76, 77], 1000 parts by weight of poly(vinyl acetate) are dissolved in 2000 parts of pure acetic acid; a mixture of 875 parts of 30 % formalin and 70 parts of concentrated sulfuric acid is added; and the mixture is stirred for 6 h at 85 °C. After the mixture is cooled to 50 °C and the sulfuric acid is neutralized, poly(vinyl formal) is precipitated with water and washed. A pale yellow powder is obtained. Instead of acetic acid, Hoechst [78] recommends the use of ethyl acetate, optionally mixed with methanol.

By altering the proportions of starting materials and varying reaction conditions, numerous types of poly(vinyl formal) can easily be produced. For the reaction mechanism, see [79, 80].

Commercial Products. Poly(vinyl formals) are marketed by Wacker-Chemie under the name Pioloform F and by Monsanto under the name Formvar.

Properties [81, 82]. Commercial poly(vinyl formal) powders in contrast to formalized fibers from poly(vinyl alcohol), are not cross-linked. Individual types differ in molecular mass, which is usually between 15 000 and 45 000, and in the proportion of vinyl acetate units, which is usually 10 – 30 wt % of the polymer. The proportion of vinyl alcohol units is between 5 and 9 wt %.

The viscosity of polymer solutions increases not only with increasing molecular mass but also with increasing poly(vinyl alcohol) content. At the same time the glass transition temperature increases from ca. 75 to 95 °C. The softening temperature is between 140 and 170 °C, depending on molecular mass. The tensile strength of the polymers is up to 70 MPa with a fracture strain

of 30 – 70 %. Depending on the type of stabilization, polymers can withstand temperatures of 120 – 150 °C for up to 1 h. The solubility in polar solvents increases with increasing proportion of poly(vinyl acetate). Poly(vinyl formals) are insoluble in hydrocarbons and alcohols, but soluble in mixtures of alcohols and aromatic hydrocarbons.

Uses. The most important use of poly(vinyl formal) is in the production of coatings for electrical wires [81], in which the poly(vinyl formal) is combined with phenolic resins. The coatings, which are cured at elevated temperature, are insoluble, tough, and resistant to abrasion and heat, and also have very good insulating properties [83, 84]. Its use in adhesive joints [85, 86] and metal coating [81] is less important.

The use of poly(vinyl formal) for foamed plastics has frequently been proposed. To produce such foamed plastics, an aqueous solution of poly(vinyl alcohol) is foamed and formalized in the presence of a water-soluble substance such as starch or sodium chloride. After washing out, an insoluble soft and spongy material is obtained [87, 88].

Toxicity. Poly(vinyl formals) are nontoxic. Poly(vinyl formals) are therefore permitted for coatings that come in contact with food [81, 82].

2.3. Poly(Vinyl Butyral)

Poly(vinyl butyrals) are commercially the most important poly(vinyl acetals). They are produced in numerous types. In 1990, world consumption of poly(vinyl butyral) was ca. 80 000 t.

Production. For the commercial production of poly(vinyl butyrals), only those processes that start from poly(vinyl alcohol) isolated before acetalization are significant. Two important processes exist. One begins with aqueous poly(vinyl alcohol) solutions, which are reacted with *n*-butyraldehyde in the presence of mineral acid. After passage through a highly viscous intermediate stage, which the stirrer must be able to cope with, the polymer precipitates as fine grains. The reaction is then completed heterogeneously. The difficulty with this process is to achieve a sufficiently homogeneous polymer.

In the second process, an alcoholic poly(vinyl alcohol) suspension is acetalized. A homogeneous poly(vinyl butyral) solution is obtained that can be freed from insolubles by filtration. The problems of this process are the costly precipitation of the polymer and the need to recover the solvent.

The effect of production conditions on polymer properties is described in [89].

Acetalization in Water.

In the IG Farbenindustrie process [90], 40 kg of poly(vinyl acetate) is saponified in a kneader with 60 kg of methanol and 3.2 L of 10 % methanolic sodium hydroxide solution. The poly(vinyl alcohol) is centrifuged from the excess methanol and methyl acetate and, still wet with solvent, is dissolved in 230 kg of water. The solution is cooled to 0 °C, and 12 kg of butyraldehyde also cooled to 0 °C, is added; the mixture is stirred for 10 min, and 50 kg of 18 % hydrochloric acid is added in one batch. After 2 min a viscous mass forms, which after another 2 min thins again. The mixture is stirred for 30 min at 0 °C, then slowly heated to 40 °C or higher, depending on whether a finer or coarser powder is desired. After cooling, the product is filtered by suction, washed with water until neutral, and dried at 40 °C.

In the Du Pont process [91], poly(vinyl alcohol) is reacted with butyraldehyde in water at 90 °C in the presence of sulfuric acid and *p*-toluenesulfonic acid. Agglomeration of the polymer that precipitates is prevented by a small amount of sodium lauryl sulfate.

Acetalization in Alcohols.

In the Hoechst process [92], 250 parts by weight of poly(vinyl acetate) is dissolved in 750 parts of methanol and 90 % saponified with one part of sodium hydroxide in 10 parts of methanol under reflux. Then, 84 parts of butyraldehyde and 35 parts of 30 % hydrochloric acid are added, and acetalization is carried out for 6 h at 60 °C. The solution is filtered, and the polymer is precipitated in fine-grained form by adding ice-cold distilled water.

Shawinigan Resins describes the saponification of poly(vinyl acetate) in ethanol in the presence of sulfuric acid for 6 – 7 h at 75 °C [93]. The separated poly(vinyl alcohol) is suspended moist in ethanol, and after sulfuric acid has been added, it is acetalized with butyraldehyde for 1 – 2 h at the boiling point.

Commercial Products. Poly(vinyl butyral) is sold as a powder. The most important manufacturers are Hoechst (Mowital B), Wacker-Chemie (Pioloform B), Monsanto (Butvar), Rhône-Poulenc (Rhovinal B), Sekisui Chem. Ind. (S-lec), and Union Carbide (Vinylite).

Properties. The interest in poly(vinyl butyrals) is based on their structure, which consists of reactive, markedly hydrophobic and hydrophilic polymer units, the ratio between the two groups being variable within wide limits.

The hydrophobic vinyl butyral units give the polymer good thermoplastic processibility, solubility in numerous solvents, elasticity, and toughness, as well as compatibility with many resins and plasticizers. The hydrophilic vinyl alcohol units are responsible for the high adhesion to inorganic materials such as glass and metals, high strength, cross-linking ability, and anticorrosive action.

Poly(vinyl butyrals) are amorphous and transparent. At low degrees of acetalization they are water soluble. Like vinyl alcohol – vinyl acetate copolymers, they are good dispersants [94]. Also like these copolymers, their solubility in water decreases with increasing temperature [95].

More highly acetalized poly(vinyl butyrals) with ca. 1 – 3 wt % of vinyl acetate units are commercially more important. They differ considerably, however, in their molecular mass and degree of acetalization.

Table 1 lists the composition and some average properties of various poly(vinyl butyrals), derived from product information pamphlets [81,96,97]. Their accuracy is, however, sufficient to show the effect of molecular mass on rheological, thermal, and mechanical properties. In addition, the effect of the proportion of vinyl alcohol units in the polymer is recognizable: with increasing vinyl alcohol content the intermolecular forces increase, and the strength and modulus of elasticity rise as do the softening point and the glass transition temperature.

In comparison with poly(vinyl formal), poly(vinyl butyrals) have a lower strength and lower modulus of elasticity. They are softer and more extensible. Their density is ca. 1.1 g/cm^3. All poly(vinyl butyrals) are soluble in $C_2 - C_4$ alcohols, glycol ethers, and alcohol – aromatic mixtures, but insoluble in aliphatic hydrocarbons.

Their compatibility with plasticizers such as esters of phthalic, sebacic, ricinoleic, and citric acids is good [98]. Other important plasticizers are ethers and esters of ethylene glycol, and esters of its oligomers with butyric or hexanoic acid. Dihexyl adipate is also used as a plasticizer for poly(vinyl butyral) [99].

Uses. The most important uses of poly(vinyl butyral) are in the manufacture of laminated glass sheets and paints.

Laminated Glass Sheets. This field of application, in which poly(vinyl butyral) is almost without competition, has become very important.

The only industrial process for producing poly(vinyl butyral) sheets is extrusion. Poly(vinyl butyral) powder is mixed with ca. 30 wt % of a plasticizer and extruded above 150 °C [100,101]. The most frequently used plasticizer is the di-2-ethylbutyric acid ester of triethylene glycol (Flexol 3 GH, Union Carbide).

A high-strength sheet is required to achieve high puncture resistance of the glass composite. Only high molecular mass poly(vinyl butyral) with ca. 17 – 22 wt % of vinyl alcohol units can meet this requirement.

In the manufacture of automobile windshields a sheet thickness of ca. 0.8 mm is generally used, whereas for structural or bullet-proof glass, thinner sheets suffice. The surface of the sheet is roughened by various techniques [100]. This reduces the tendency to stick together and facilitates deaeration during production of the glass composite. To completely prevent sticking, the sheet is either dusted with sodium hydrogencarbonate, which must be washed off before producing the composite, or cooled below 10 °C.

In manufacturing the composite [102], sheets are laid between two or more sheets of glass and subjected in an autoclave to a special pressure and temperature program [103].

Accurately defined adhesion of the plastic sheet to the glass is particularly important [104]. Upon impact of a foreign body on the composite, the glass breaks first. If the sheet adheres very firmly to the glass, it is at once overstretched and tears when the glass breaks, and the composite

Table 1. Properties of poly(vinyl butyrals) with various percentages of vinyl alcohol units and various molecular masses

is punctured. The adhesion must therefore be reduced so that when the glass breaks the sheet detaches slightly and a larger area can then absorb the impact elastically. However, the adhesion must not be so low that splinters of glass become completely detached from the sheet.

The adhesion of poly(vinyl butyral) sheets to glass is normally too high, and numerous substances are known that cause a defined reduction. These include particularly salts, of which various potassium salts such as potassium acetate are especially important [105]. Lecithin is also highly effective [106].

Plasticized poly(vinyl butyral) sheets for the production of automobile windshields and structural or bullet-proof glass are sold, for example, by the following companies: Du Pont

(Butacite), Dynamit Nobel (Trosifol), Fatra Napajedla CSFR (Butaflex), Monsanto (Saflex), and Sekisui Chem. Ind. (S-lec Sheet). Monsanto and Du Pont have the largest market shares.

Paints. Because of their elasticity and good adhesion, poly(vinyl butyrals) are important raw materials for paints, particularly for metal coatings. They are frequently combined with phenolic, alkyd, epoxy, urea, or melamine resins. The low-acetalized and lower molecular mass types, in particular, show good compatibility with these resins. When the coatings are baked, cross-linking occurs [107].

Poly(vinyl butyrals) are outstandingly effective as primers with high corrosion protection. In wash primers they are used in dissolved form (e.g., together with pigments, chromium salts, and phosphoric acid). Shop primers, which are used especially in shipbuilding for priming metal plates, must have extended durability. In addition to poly(vinyl butyral) and solvents, they contain, for example, a phenolic resin, zinc chromate, iron oxide, and phosphoric acid. The coatings are abrasion resistant and adhere very well. The coated plates can be welded easily [96, 108].

In addition, poly(vinyl butyrals) are used as binders in special paints (e.g., for leather or plastics), as well as in printing inks [109].

Poly(Vinyl Butyral) Dispersions. When poly(vinyl butyral) is used dispersed in the aqueous phase, pollution of the environment by solvents is avoided. Nevertheless, such dispersions have minor importance because of their high price and their relatively high emulsifier content, which impairs the adhesive properties and water resistance of coatings. Poly(vinyl butyral) dispersions can be produced by acetalization of aqueous poly(vinyl alcohol) solutions in the presence of an emulsifier or by emulsification of poly(vinyl butyral). A plasticizer-containing dispersion is sold by Monsanto under the name Butavar Dispersion BR for use as a textile coating [81].

Other uses for which poly(vinyl butyrals) have been proposed are adhesives [107]; temporary, strippable coatings [110]; powder coatings [111]; and blends with other polymers.

Toxicity. Poly(vinyl butyrals), like poly(vinyl formals), are nontoxic and permitted by law in packaging for foodstuffs [81, 96].

2.4. Other Poly(Vinyl Acetals)

The numerous aldehydes that have been reacted with poly(vinyl alcohol) include furfural, benzaldehyde, crotonaldehyde, halogenated aldehydes, cyanopropionaldehyde, nitrobenzaldehyde, and glyoxylic acid. Nothing is known about the economic importance of the poly(vinyl acetals) prepared from them. Poly(vinyl acetaldehyde acetal), on the other hand, temporarily played a role in Germany and Canada, but was displaced by poly(vinyl butyral) [112].

Studies of poly(vinyl acetals) from aliphatic C_2-C_8 aldehydes with different acetal contents in the presence and absence of plasticizers [113] have shown that the glass transition temperature decreases with increasing chain length of the aldehyde component. At the same time the poly(vinyl acetals) become softer and more hydrophobic.

Of the poly(vinyl acetals) from substituted aldehydes, the sodium salt of poly(vinyl butyral sulfonic acid) is produced commercially (Afrilan, Hoechst). The substance is water soluble and is important in sizing. It is produced by passing sulfur dioxide into an aqueous solution of poly(vinyl alcohol) in the presence of crotonaldehyde at 0 °C and then heating the solution. Sulfurous acid adds to crotonaldehyde simultaneously with acetalization, and the sulfonic acid formed acts as catalyst for the acetalization, so that further addition of acid is unnecessary [114].

3. Poly(N-Vinyllactams) and Poly(N-Vinylamines)

3.1. Polyvinylpyrrolidone

When *N*-vinylpyrrolidone and other *N*-vinyl compounds became commercially available by Reppe vinylation of lactams in about 1940, the polymers were soon produced on an industrial scale. Polyvinylpyrrolidone is used as an auxiliary in cosmetics and pharmaceuticals.

N-vinylpyrrolidone

Production. Only radical polymerization is important. *N*-vinylpyrrolidone (*mp* 13.9 °C, *bp* at 1.3 kPa 90–93 °C) is usually polymerized batchwise in aqueous solution with hydrogen peroxide as initiator and regulator. The average molecular mass can be adjusted by varying the quantity of hydrogen peroxide: with 0.05 % hydrogen peroxide, molecular masses of ca. 750 000 are obtained; with 3 %, ca. 25 000. With increasing quantity of hydrogen peroxide the polymerization rate increases. The rate also increases with increasing concentration of *N*-vinylpyrrolidone in the aqueous solution, reaches a maximum at 40–60 % monomer content, and then decreases. Due to the viscosity of the final polymer solution the concentration is adjusted within a range between 10 % at high molecular mass and 60 % at low. To control polymerization, the monomer solution must be added slowly to the polymerization mixture with cooling. Polymerization is complete after 6–12 h. The ready saponifiability of *N*-vinylpyrrolidone in aqueous acidic solution is a problem. Aqueous solutions containing monomeric *N*-vinylpyrrolidone should therefore always be neutral to basic. The pH value is best controlled with ammonia, which also activates the polymerization reaction [115].

Polyvinylpyrrolidone can be obtained as a white powder from polymer solutions by drum or spray drying. Because it is highly hygroscopic it must be protected from moisture during extended storage.

Polymerization can also be carried out in organic solvents. The initiators preferably used then are organic peroxides or azocompounds, preferably alkyl hydroperoxides, dialkyl peroxides, and peroxy esters [116]. The polymerization temperature is chosen according to the decomposition temperature of the initiator, but the polymerization rate also depends on the nature of the solvent [117, 118].

Bulk polymerization [119] and polymerization in suspension [120] have no commercial importance.

N-Vinylpyrrolidone can be copolymerized with many other vinyl compounds such as acrylic acid [119, 121, 122], methacrylates esters [115, 123], and methacrylamide [124]; for the *Q* and *e* values, see [125]. The most important are the polymers with vinyl esters [124, 126, 127],

whose properties lie between those of the pure polymers.

When *N*-vinylpyrrolidone is heated for several hours with hydroxides and alkoxides of the alkali and alkaline earth metals [128], an insoluble polymer slightly swellable by water is formed in a spontaneous reaction. This polymer is also formed on heating *N*-vinylpyrrolidone with divinyl compounds in the absence of atmospheric oxygen [129] and is known as popcorn polymer [130].

Commercial Products. Polyvinylpyrrolidones with an average molecular mass of 2500 to 750 000 are on the market.

Trade names are Kollidon, Luviskol, Albigen A, and Divergan (BASF); PVP and Plasdone (General Aniline and Film Corp.); Collacral and Luviskol VA (copolymers with vinyl esters, BASF); PVP/VA (copolymers with vinyl acetate, General Aniline and Film Corp.); Polyclar and Polyplasdone XL (insoluble polyvinylpyrrolidone, General Aniline and Film Corp.).

Properties. Polyvinylpyrrolidone is a white powder. The glass transition temperature depends on the water content; extrapolation to 0 % water content gives a glass transition temperature of 175 °C. The mean molecular mass can be adjusted in the range of 1000 to 10^6.

Polyvinylpyrrolidone is highly hygroscopic, absorbing ca. 30 % water at 60 % humidity. It dissolves readily in water, and aqueous solutions are stable to electrolyte addition. The viscosity of the solution decreases with increasing temperature and with strong shearing [131].

Polyvinylpyrrolidone dissolves readily in polar solvents such as alcohols, amines, acids, and chlorinated hydrocarbons. It is insoluble in esters, ethers, ketones, and hydrocarbons. Completely anhydrous polyvinylpyrrolidone is also soluble in toluene.

Polyvinylpyrrolidone can be precipitated from aqueous solution by dropwise addition to acetone and from solution in organic solvents by addition of diethyl ether.

Polyvinylpyrrolidone has good compatibility with numerous film formers, water-soluble binders, and plasticizers. On solution casting, a clear, high-gloss, hard film is formed.

The polymer is chemically inert. The lactam group is saponified only by the action of concentrated acids, with the formation of poly[vinyl(γ-amino)butyric acid] [132].

With some substances such as iodine, polyphenols, tannin, dyes, and toxins, polyvinylpyrrolidone forms complexes [133]. Frequently, only a reversible association occurs. The protective colloid action is utilized in dispersions and in suspension polymerization.

For qualitative analysis [134], aqueous ammonium cobalt thiocyanate solutions are added to an acidic aqueous polyvinylpyrrolidone solution. The flocculation of a bright blue complex indicates polyvinylpyrrolidone. The IR spectrum is also suitable for identification. To determine concentration, the brownish red polyvinylpyrrolidone – iodine complex can be analyzed colorimetrically.

Uses. In cosmetics, polyvinylpyrrolidone and some copolymers, especially with vinyl acetate, are used as film formers in setting lotions and hairsprays. Fairly high molecular mass polyvinylpyrrolidone is used as a thickening agent and protective colloid in cosmetic emulsions. Its use as a blood plasma substitute has been abandoned.

In pharmacy, polyvinylpyrrolidone has a wide spectrum of applications: as a solubilizer, as a crystallization retarder, for detoxification, for reducing the irritant action and toxicity of certain substances, as a tablet binding and coating agent, as a suspension stabilizer, and as a dispersant for pigments in tablet-coating suspensions. The polyvinylpyrrolidone (PVP) complex with iodine, PVP-iodine, is used as a disinfectant and does not show the side effects of elementary iodine [135]. The insoluble and slightly water-swellable popcorn polymer is used as a tablet-disintegrating agent. Polyvinylpyrrolidone and PVP-iodine are described in a series of pharmacopoeias (e.g., in the U.S.).

Since polyvinylpyrrolidone forms complexes with tannins it is used for the clarification of beer and other beverages. The cross-linked, insoluble popcorn polymer is particularly suitable [136].

Polyvinylpyrrolidone forms hard, transparent, strongly adherent films on glass, metal, plastics, and cellulose, and is used in the adhesives industry as a binder and water-soluble hot-melt adhesive.

Polyvinylpyrrolidone is also used as an auxiliary in textile finishes, as a dye acceptor for synthetic fibers, as a leveling and stripping agent for dyes, as a thickener for printing inks and latex paints, as a dispersant in laundry detergents, as a protective colloid in the emulsion and suspension polymerization of many polymers, and as a water-binding agent for the concentration of protein solutions [137].

Toxicology. Polyvinylpyrrolidone is chemically and biologically largely indifferent [138, 139] with regard to both acute toxicity and skin irritation.

In feeding tests on rats with radioactively labeled polyvinylpyrrolidone of average molecular mass 40 000, more than 99 % was excreted through the intestinal tract [138]. Even when large amounts of polyvinylpyrrolidone were fed for years, no harm to experimental animals was established. Swelling of the lymph nodes, which can be interpreted as a transition stage in the excretion of polyvinylpyrrolidone, was observed only with dogs; no indications of accumulation or extensive degenerative changes to organs were detected.

Carcinogenicity of polyvinylpyrrolidone was not observed in any of the experimental procedures [140]. On the basis of extensive experience on humans as well as on the results of further experimental studies on animals with parenteral or oral administration, no evidence of carcinogenic risk to humans was found [141].

More than one million people have shown good tolerance for polyvinylpyrrolidone infusions as a blood plasma substitute without side effects. However, the high molecular mass fractions of polyvinylpyrrolidone, with molecular masses above 40 000, are excreted slowly or not at all. Polyvinylpyrrolidone is therefore no longer used for infusions because the low molecular masses types do not have a plasma-expander action. Animal experiments have shown that larger molecules are stored in the cells of the reticuloendothelial system of the spleen, the liver, and the lymph nodes, as well as in bone marrow. However, during such polyvinylpyrrolidone storage, neither morphological nor functional damage has been observed [142].

On the basis of inhalation tests on female volunteers with six different kinds of hairspray that caused no pathological changes of any kind [143], the FDA reported that the normal use of aerosol hairsprays containing PVP and PVP–vinyl alcohol as film formers is not accompanied by a health risk.

3.2. Polymers of other *N*-Vinyllactams

In the addition to polyvinylpyrrolidone, the polymers of other *N*-vinyllactams such as *N*-vinylpiperidone [137] and *N*-vinylcaprolactam [144] are known.

N-vinylpiperidone

N-vinylcaprolactam

These polymers have better solubility than polyvinylpyrrolidone in organic solvents such as aromatic hydrocarbons, ketones, and aliphatic hydrocarbons. Polyvinylcaprolactam is readily soluble in cold water: the higher its average molecular mass, the better is its solubility. In warm water (30 – 40 °C), polyvinylcaprolactam precipitates from solution.

Vinylcaprolactam can be polymerized in bulk [145] or in solution. The polymers are used for gluing woven synthetic textiles and as components of lubricating oils [146]. The copolymers with ethylene are used as coatings for textiles and paper, and as adhesives [147].

3.3. Polyvinylamines

Poly(*N*-vinylcarbazole) is a transparent thermoplastic material. The glass transition temperature is 211 °C and the glass point 173 °C. It starts to decompose only above 300 °C [148].

Vinylcarbazole

Poly(*N*-vinylcarbazole) dissolves in aromatic and chlorinated hydrocarbons and in tetrahydrofuran. It swells in benzene-containing fuels and is insoluble in water, dilute acid and alkali, aliphatic hydrocarbons, and alcohols.

The electrical properties are unusual. Photoconductivity depends on the molecular mass [149]; doping effects are observed upon addition of various substances such as 1,5-diaminonaphthalene, tetracyanoethylene, or anthracene [150]. The existence of traps for electronic charge carriers (electrons and defect electrons) has been demonstrated [151]. For the mechanism of conductivity, see [152].

Before polymerization, *N*-vinylcarbazole (*mp* 63 – 64 °C, *bp* at 0.3 kPa 155 °C) should be purified by distillation or recrystallization. When handling *N*-vinylcarbazole, safety instructions should be observed [153], because it has very strong sensitizing properties. No harmful side ef-fects are known for monomer-free poly(*N*-vinylcarbazole).

For radical polymerization in bulk, azo initiators or peroxides are used [154, 155]. Suspension polymerization in water [156] or methanol [157] is also known. Cationic polymerization of *N*-vinylcarbazole proceeds easily, but whether polymerization in the presence of benzoyl peroxide occurs via a radical or a cationic route is unknown [158]. Cationic polymerization has a rate constant five times higher than radical polymerization and is used for the production of low molecular mass polymers [159].

Radical copolymerization with other vinyl compounds such as styrene, acrylonitrile, vinyl esters, and acrylate esters has been described, and a Q value of 0.28 and an e of -1.49 are given [160]. The stereospecific polymerization of *N*-vinylcarbazole is also known [161].

Because its softening point is ca. 200 °C, polyvinylcarbazole was formerly used for moldings that are exposed to elevated temperature. Fibers and films have also been manufactured from polyvinylcarbazole [162]. Today, it is used as a heat-resistant insulator in radio and radar technology and in capacitor manufacture [163]. Because of its photoconductivity it is important for the manufacture of electrostatic photocopiers and television recording tubes [164].

Commercial Product: Luvican (BASF).

Polyvinylimidazole. Because of the second nitrogen atom, polymers of *N*-vinylimidazole have a basic character. The solubility therefore depends on the degree of protonation. Unquaternized polyvinylimidazole is soluble in organic solvents such as alcohol, but in water it is only swellable. It dissolves in acids, with salt formation. Quaternized polyvinylimidazole is water soluble. Depending on the length of the alkyl group used in quaternization, polymers with different hydrophobic – hydrophilic character are obtained [165].

N-vinylimidazole (*bp* 190 – 193 °C) and *N*-vinylimidazoles quaternized with alkyl halides or dialkyl sulfates can be polymerized by the radical mechanism using azo initiators and peroxides. Copolymerization with acrylamide, acrylates, butadiene, styrene, *N*-vinylpyrrolidone, and vinyl acetate has been described: values of 0.1 and 0.24 have been given for Q, and -0.91 and -1.73 for e [166].

N-vinylimidazole

Polyvinylimidazole and copolymers are used as hairdressing preparations, antistatic agents for hydrophobic plastics, liquid detergents, and in the production of hydrogels.

Other Vinylamines. Because of their instability, aliphatic vinylamines can be prepared only with difficulty, and the corresponding polyvinylamines are obtainable only by indirect routes [167]. Cyclic amines such as carbazole and imidazole, indole, and pyrrole, on the other hand, can easily be converted to *N*-vinylamines by Reppe vinylation.

Polymers of 2-vinylpyridine and 4-vinylpyridine have also been produced. 4-Vinylpyridine can be copolymerized with other vinyl compounds such as styrene and vinyl chloride; values of 1.91 for Q, and -0.51 for e are given [168]. Polyvinylpyridines have been studied as polymeric reagents in organic synthesis, catalysts, and ion exchangers.

1. Introduction [1-12]

Alphons C. J. Voragen

For a general definition of the term polysaccharides, see ⟶ Carbohydrates.

Polysaccharides made up of only one type of neutral monosaccharide structural unit and with only one type of glycosidic linkage — as in cellulose or amylose — are denoted as *perfectly linear* polysaccharides. In branched polysaccharides the frequency of branching sites and the length of the side chains can vary greatly. Molecules with a long “backbone” chain and many short side chains are called *linearly branched* polysaccharides.

Polysaccharides are water soluble or swell in water, giving colloidal, highly viscous solutions or dispersions with plastic or pseudoplastic flow properties. Functional properties such as thickening, water holding and binding, stabilization of suspensions and emulsions, and gelling, are based on this behavior. Therefore, polysaccharides are often referred to as gelling or thickening agents, stabilizers, water binders, or fillers. A more generic name is gums. The terms hydrocolloids or, in the food industry, food colloids are also in use, but they include proteins with similar functional properties.

In this article the economically important polysaccharides, with the exception of starch (see ⟶ Starch) and cellulose (⟶ Cellulose) are described. Table 1 lists the polysaccharides, and gives an overview of their sources and composition. Their most important and various applications are summarized in Table 2. In only a few cases is their use specific. Examples are the use of pectin in commercial jam and marmalade production, where its heat stability coincides with its ability to gel in the typical pH range of these products, or the stabilization of drinking chocolate with carrageenan, which has a specific interaction with milk proteins and chocolate particles. In many cases, the manufacturer has various options and price plays an important role. For papermaking choice may be between, for example, alginates, galactomannans, and starch derivatives; for oil drilling, xanthan, starch derivatives, cellulose derivatives, galactomannans, or alginates can be used. Milk gels can be prepared with pectin, starch, alginates, or carrageenans. Often mixtures of polysaccharides are preferred to single polysaccharides because they combine various desirable properties (e.g., in ice cream or salad dressing). In a number of cases a synergistic interaction on the molecular level between polysaccharides can be exploited (e.g., improvement of the structure of carrageenan gels by the addition of guar gum or the preparation of gels by mixing xanthan and locust bean gum).

Table 1. Origin and main sugar moieties of polysaccharides

Name	Origin	Main sugar moieties
Pectin	cell walls and middle lamella of higher land plants	D-galacturonic acid D-galacturonic acid methylester
Alginate	cells walls of brown seaweeds exopolysacchrides of *Azetobacter vinelandii*	D-mannuronic acid L-guluronic acid and their acetyl derivatives
Carrageenan	cell walls of red seaweeds	D-galactose 3,6-anhydro-D-galactose both sugars sulfated to higher or lower degree
Agar	cell walls of red seaweeds	D-galactose 3,6-anhydro-L-galactose few sulfate groups
Gum arabic	exudate of acacia species	L-arabinose, D-galactose L-rhamnose, (4-*O*-methyl) D-glucuronic acid
Gum tragacanth	exudate of astragalus species	L-arabinose, D-galactose D-galacturonic acid methylester D-xylose, L-rhamnose, L-fucose
Gum karaya	exudate of sterculia species	D-galacturonic acid, L-rhamnose, D-galactose D-glucuronic acid
Gum ghatti	exudate of *Anageissus latifolia*	L-arabinose, D-galactose D-mannose, D-xylose, D-glucuronic acid, L-rhamnose
Guar gum	endosperm of seeds of the guar plant (*Xyampsis tetragonolobus* L. Taub)	D-mannose D-galactose
Locust bean gum	endosperm of the seeds of the carob tree (*Ceratnia siliqua* L.)	D-mannose D-galactose
Tara gum	endosperm of the seeds of the tara tree (*Caesalpinia spinoza*)	D-mannose D-galactose
Xanthan gum	exopolysaccharide of *Xanthomonas campestris*	D-glucose, D-glucoronic acid, D-mannose substituted with acetate or pyruvate groups
Gellan gum	exopolysacchride *Pseudomonas elodea*	D-glucose, D-glucuronic acid, L-rhamnose

Table 2. Areas of application of polysaccharides *

Foods (⟶ Foods, 3. Food Additives)

1. Thickening and gelatinizing of fruit with a higher or lower content of sugar: preserves, marmalades, jellies, fruit for yogurt and ice cream, marmalade for cooking.
2. Gelatinizing of heat-reversible jelly and sugar glaze. Jellied sugar products, jellied sweets, dessert jellies (powder form).
3. Prevention of starch breakdown in bread and baked products, and in fruit-filled products based on starch (⟶ Bread and Other Baked Products).
4. Cloud stabilization in fruit juice. Providing body in refreshing powdered drinks (⟶).
5. Stabilization of powdered flavor emulsions. Microencapsulation of flavorings (⟶ Microencapsulation).
6. Gelatinization and thickening of milk: puddings and cream for hot and cold preparations; also as powdered instant products (⟶).
7. Stabilization of chocolate milk and evaporated milk: prevention of sedimentation or separation of the cream fraction (⟶).
8. Stabilization of ice cream: prevention of formation of ice crystals and dripping. Stabilization of the fat emulsion, imparting favorable slip properties for mold release (⟶).
9. Water binding in cream cheese-type spreads, soft cheese, and cheese preparations.
10. Stabilization of fat emulsion in powdered coffee whiteners and low-fat margarine.
11. Stabilization of egg-white froth, whipped cream, and imitation whipped cream, meringues, and beer foam.
12. Stabilization and thickening of soups, sauces, dips, salad cream, mayonnaise, catsup, etc. Prevention of syneresis. Imparting freeze – thaw stability, and body in fat and starch-reduced products.
13. Binding agents in ground meat products (e.g., corned beef, sausages) and in canned dog and cat foods.
14. Gelatinized (jellied meat) or thickened stock from meat, fish, and vegetables.
15. Binding agents for (potato flour) snacks.

Cosmetics

16. Thickening agents in creams, ointments, lotions, and hair gels (⟶ Skin Cosmetics).

Household Goods and Industry

17. Solid air fresheners.
18. Stabilization of emulsified and suspended active agents in insecticides and herbicide sprays.
19. Stabilization of suspended abrasion materials in polishes and cleaning agents.
20. Glue.

Pharmaceuticals

21. Thickening agents in creams, lotions, ointments, and syrups.
22. Toothpaste (water-binding, consistency, ⟶ Dental Materials).
23. Denture adhesives.
24. Tablet-binding agents.
25. Dental impression materials (⟶ Dental Materials).

Industry

26. Binding agents in explosives.
27. Binding agents for layered coating of welding electrodes.
28. Different functions of the rinsing liquid used in deep drilling technology.
29. Paper binding agents. Paper coating agents (fat-resistant properties, improved printability, uniform distribution of pigment despite extremely high speeds of modern papermaking machines (⟶ Paper and Pulp, Production); additives to improve absorbency.
30. Sizing and finishing agents used in the textile industry (⟶ Textile Auxiliaries).
31. Thickening of textile printing pastes and coloring agents to ease application and prevent color bleeding.
32. Flocculation agents for water processing (⟶ ; ⟶ Wastewater).
33. Pigment stabilization and paint consistency (thixotropy in emulsion paints).

---

* The numbering has been introduced merely to allow reference in the text and does not rank the applications in order of importance.

2. Analysis and Characterization

Alphons C. J. Voragen

The analysis and characterization of polysaccharides can be aimed at the following:

1. Estimation of their content in raw materials
2. Qualitative and quantitative identification of one or more polysaccharides in a preparation
3. Qualitative and quantitative identification of one or more polysaccharides in a (food) product
4. Estimation of specific properties such as gelling strength or viscosity
5. Estimation of specifications for purity (e.g., color, content of heavy metals or cations, moisture, ash, or microbial count)

The manufacturer is interested primarily in item 1); items 2) and 3) are of concern to the user and 3) for state inspection services; item 4) is of interest to the manufacturer in terms of standardization, and the user in terms of applications; item 5) is of particular interest to the consumer and to state inspection services in pharmaceutical and food applications.

For determination of items 2) and 3), several possiblities exist [13], [14]. In most cases, solutions or extracts must be prepared in which the polysaccharides are estimated qualitatively by precipitation reactions [15], or a special analytical procedure is used to separate anionic polysaccharides from neutral polysaccharides by precipitation with cetylpyridinium chloride [16], [17]. When the necessary equipment is available, quantitative analysis, based on the gas chromatographic determination of the constituent sugar moieties after hydrolysis and derivatization of the purified polysaccharide is often quicker and more reliable [29]. Recently, HPLC has been used more often in the analysis of constituent sugar moieties. Another new development is the use of immunological methods based on the development of antibodies against the polysaccharides. The requirements indicated under item 5) and the corresponding analytical methods are defined in pharmacopeias, food legislation, and specifications of national and international organizations [41, 62, 63]. The latter also describe identification reactions. Additional information on the analysis of individual polysaccharides is given in the corresponding sections.

[Top of Page]

3. Pectin

Alphons C. J. Voragen, Claus Rolin, Beinta U. Marr

Pectin or pectic substances, also called galacturonans or rhamnogalacturonans in scientific literature, is a collective name for heteropolysaccharides that consist predominantly of partially methylated galacturonic acid residues [18, 74, 85, 96, 104-111]. The name pectin (Greek: *Pectos* = gelled) was coined by BRACONNOT [112] who first described this compound in detail in 1825 and indicated its primary use as a gelling agent. Native pectin plays an important role in the consistency of fruits and vegetables, and in textural changes during ripening and storage [85], [113]. The often desired cloud stability of fruit juices and fruit drinks is lost when enzymes endogenous to the fruit degrade pectin (tomatoes) or cause it to precipitate as calcium pectate after demethylation. On the other hand, enzymes may be added as processing aids to degrade native pectin, for example, to apple juice to facilitate clarification or to the pulp of berries to improve press and color yield [114-116]. Pectin is extracted on an industrial scale from the press residues in apple and citrus juice manufacture and used mainly as gelling and stabilizing agents in the food industry [117].

3.1. Occurrence and Structure

Occurrence. Pectins occur in virtually all higher plants, Zosteraceae seaweed, and certain freshwater algae. Pectins are major structural components of the primary cell wall and the middle lamella of young growing plant tissues (meristimatic and parenchymatic) but do not occur in more mature tissue. The composition of the cell wall therefore is of major importance in the texture of fruit and vegetables [19], [20]. The primary cell wall consists of 90 % polysaccharide and 10 % glycoprotein on a dry matter basis [21]. The polysaccharide composition is 30 – 60 % cellulose, 15 – 45 % pectic substances, and 15 – 25 % hemicellulose [22]. A schematic structure of the plant cell wall is illustrated in Figure 1.

Figure 1. Schematic structure of the plant cell wall [23]

The biosynthesis of pectin takes place in the cell plate during cell division. Pectin is formed as polygalacturonic acid with UDP-D-galacturonic acid — arising from UDP-D-glucose by an epimerase- catalyzed reaction — as the most active glycosyl donor. Immediately after the galacturonan chain has been formed, methoxyl groups are formed with *S*-adenosylmethionine as the methyl group donor [120].

Pectic substances can be partially solubilized from plant tissues without degradation by using weakly acidic, aqueous solvents with or without calcium chelating agents. The pectin fraction that is not extractable with these extractants because of its attachment to other cell wall components by chemical, physical, or mechanical (enmeshment) bonds, is often designated as *protopectin*. Commercial pectin extraction must break down protopectin to a soluble, high molar mass pectin. This is achieved by acid hydrolysis in which, on the one hand, the molar mass of pectin molecules is lowered and, on the other hand, connections to the hemicellulose fractions are split. This transition from protopectin to soluble pectin also occurs during ripening of fruit or cooking of vegetables, resulting in textural changes [85], [113]. Pectin technology is therefore interested in the nature of protopectin and its fixation in the cell walls in an attempt to develop more efficient methods of extraction. FRY [119] has discussed cross-links in cell walls and agents used to cleave the individual bonds. Pure enzymes may also be used for extraction of firmly bound pectin [24], [25].

Structure. Pectin is composed of 1,4-linked α-D-galactopyranosyluronic acid units in the $^4C_1$ conformation, with the glycosidic linkages arranged diaxially (Fig. 2). A proportion of the carboxyl groups is esterified with methanol. Commercial pectins are divided into low-ester and high-ester pectin. In *low-ester pectins (LM-pectins)* less than 50 % of the carboxyl groups are methylated (typical range is from 20 to 40 %) whereas in *high-ester pectins (HM-pectins)* more than 50 % are methylated (typical range is from 55 to 75 %). If less than 10 % of the carboxyl groups are methylated the polysaccharide is called *pectate* or *pectic acid*. Pectins prepared from pears, potatoes, sugar beets, and sunflower heads are acetylated to varying degrees at the secondary hydroxyl groups of the galacturonic acid residues [118].

Figure 2. α-D-Galactopyranosyluronic acid in $^4C_1$ conformation (above); fragment of galacturonan chain, 40 % methylated (below)

The heteropolysaccharide nature of pectin derives from the fact that other sugars are incorporated in the pectin molecule. The most common ones being L-rhamnose (Fig. 3), occasionally inserted by α-1,2-linkages in the galacturonan backbone, providing “kinks” in the molecular chain. Other sugars are β-D-xylose, attached as single-unit side chains mainly to O-3 of the galactopyranosyluronic acid residues in the backbone; and D-galactose and L-arabinose, which occur in long side chains, only attached to rhamnopyranosyl residues (for projection formulae, see ⟶ Carbohydrates).

Figure 3. 1,2-Linked L-rhamnopyranosyl unit in $^1C_4$ conformation

The frequency of rhamnose occurrence remains to be established, however it has been suggested that α-rhamnosyl units are concentrated in rhamnose-rich areas. In other words, the soluble pectin is built up of homogalacturonan-dominated areas, so-called *smooth regions* linked to rhamnogalacturonan areas rich in neutral sugars, so-called *hairy regions* (Fig. 4). The neutral sugars account for 10 – 15 % of the weight of the pectin. In the hairy regions, the neutral sugar chain length may be in the range 8 to 20 residues [26], [27]. By degradation with chemical β-elimination and endo-polygalacturonase, it was found that 90 % of the rhamnose units are found in the hairy region [28], [30].

Figure 4. Schematic representation of pectin backbone, showing the “hairy” regions (rhamnogalacturonan and side-chains) and the “smooth” regions (linear galacturonan) [31]

By acid hydrolysis, i.e., splitting the acid labile glycosidic bonds between rhamnose and galacturonic acid, nearly pure homogalacturonic acids with molecular masses in the range 20 000 to 25 000 have been obtained [32], [33]. This corresponds to a chain length of 75 to 100 galacturonic acid residues. For comparison, a molecular mass of 90 000 has been quoted for intact pectin [34], but the molecular mass of pectin is somewhat

uncertain (see Section Chemical Analysis).

Commercial pectins may also contain neutral polysaccharides that are not covalently attached to the pectic backbone, such as galactans, arabinans, arabinogalactans, and starch, often referred to as “ballast” compounds. Purified pectins prepared from apple pomace or citrus peel may contain 75 – 90 % anhydrogalacturonic acid on an ash- and moisture-free basis.

3.2. Pectolytic Enzymes

Pectins can be attacked by various enzymes [114], [115], [121]. The significance of native pectic substances in food technology can be evaluated properly only when the activity of these enzymes is taken into account.

Pectinesterase (PE, pectin methylesterase, pectase, pectin demethoxylase, pectin pectylhydrolase, EC 3.1.1.11) splits off the methoxyl groups and converts high-methoxyl pectins to low-methoxyl pectins. The latter are extremely sensitive to complex formation and precipitation with Ca^{2+} ions, particularly when a pectinesterase of plant origin is used. This type of enzyme does not saponify methyl esters in a random fashion as microbial PEs do, but acts along the galacturonan chain, creating blocks of free carboxyl groups. Pectinesterase occurs in many higher plants, particularly tomatoes, citrus, and other fruits; it is also produced by many fungi and bacteria.

Polygalacturonase (PG, pectinase, pectate hydrolase, poly- α-1,4-D-galacturonide glycanohydrolase, EC 3.2.1.15 and 3.2.1.67) preferentially hydrolyzes low-methoxyl pectins or pectic acid because these enzymes can cleave glycosidic linkages only next to free carboxyl groups. PGs can be divided into enzymes that degrade their substrate by an endo attack (splitting randomly in the backbone, *endoPG*), and enzymes that act from the nonreducing end removing mono- or digalacturonic acid (*exoPG*). PGs are produced by fungi and certain bacteria, and also occur in higher plants (tomatoes). The endoPGs, with their strong depolymerizing action, are of particular technological importance.

Pectate lyase (PAL = pectic acid lyase, PATE = pectic acid transeliminase, LMPL = low-methoxyl pectin lyase, poly- α-1,4-D-galacturonide lyase, EC 4.2.2.2 and 4.2.2.9) also splits glycosidic linkages next to free carboxyl groups. In this group of enzymes, endo and exo enzymes also exist. The preferential substrates for *endoPAL* are LM-pectins rather than pectic acid. Pectate lyases have an absolute requirement for Ca^{2+} ions. The glycosidic linkages are split by a *trans*-elimination reaction. PALs are produced predominantly by bacteria and are not important in fruit and vegetable processing because of their high optimum pH (8.5 – 9.5).

Pectin lyase (PL, PTE = pectin transeliminase, pectinase, poly- α-1,4-D-methoxygalacturonide lyase, EC 4.2.2.10) splits glycosidic linkages between methoxylated galacturonide residues by a *trans*-elimination reaction. These enzymes therefore have a preference for HM-pectins. Pectin lyases are produced only by fungi.

A newer pectin-degrading enzyme acts in cooperation with a pectin acetylesterase only on highly branched regions of pectin to release oligosaccharides consisting of alternating sequences of α-1,2-linked L-rhamnosyl residues and α-1,4-linked D-galacturonosyl residues, with galactosyl residues β-1,4-linked to part of the rhamnosyl units. The nonreducing end is always a rhamnose unit [122], [123].

Commercially available pectinases, used on an industrial scale in fruit and vegetable processing are of fungal origin and generally contain in addition to PE, PG, and PL, proteases and various hemicellulases and cellulases.

3.3. Production [106], [109], [117], [122], [124]

The production of pectin is summarized in Figure 5.

Figure 5. Flow chart of pectin production

Raw materials of importance to pectin manufacturing are currently various kinds of citrus peel, and apple pomace. Lemon and lime are the preferred citrus sources, and more pectin is produced from these than from apple or the less preferred citrus materials, orange and grapefruit. Some of the pectin producing companies which historically developed in connection to apple production now partly or wholly base their production on imported citrus peel. Sugar beet was once used as a pectin source to some extent [35], but the pectin is inferior as a gelling agent compared to citrus or apple pectin. It has been reintroduced, and is currently being marketed as a stabilizer. Numerous other sources like mango [36], pea hulls [37], sunflower heads [38], [39], and pumpkin [40] have been suggested.

Citrus peel and apple pomace are available as byproducts from juice manufacturing. They are usually washed in water and dried before being used for pectin manufacturing, but some citrus material is used in pectin plants neighboring the juice production without previous drying. In either case processing of the raw materials has to commence immediately after juice production in order to prevent microbial degradation. The washing leaches out organic acids, sugar, and pigments and is thus one of the separation processes in the purification of pectin. Most importantly, it prevents discoloration either from browning of pigments or from caramelization during the raw materials drying.

Extraction. The pretreated raw material is extracted in water which has been acidified with e.g., hydrochloric or nitric acid. Typical conditions are: pH 1 to 3, temperature 50 to 90 °C, duration 3 to 12 h. During the extraction, limited depolymerization of the pectin and possibly of other connecting biopolymers takes place, and the pectin dissolves. The low pH further dissociates ionic linkages which hold the pectin in the plant tissue. In addition to hydrolyzing glycosidic bonds, the extraction conditions also hydrolyze ester linkages, more specifically the methyl ester at C-6, and the acetate to which pectin may be esterified by its hydroxyl groups. The extraction process thus causes a reduction in degree of polymerization as well as in degree of methyl and acetate esterification. The pectin yield increases with the acidity, the temperature, and the duration, but the product will lose too much in degree of polymerization if all these parameters are at their maximum. The combination of low pH and low temperature favors hydrolysis of ester linkages over hydrolysis of glycosidic bonds, and it is thus preferred for production of pectin with a relatively low degree of esterification.

Filtration in one or more stages separates the extract containing the solubilized pectin from the insoluble, but at this stage very soft and fragile, plant tissue. The rather difficult filtration requires reasonably low viscosity, and as a consequence the pectin concentration must be less than 0.6 to 1 %, depending upon the pectin type. Further, the solids must not have been comminuted by excessive mechanical treatment such as vigorous agitation. Water-insoluble materials like wood cellulose or diatomaceous earth may be added in order to improve the porosity and mechanical strength of filter cakes. Amylase may be added to remove starch from apple pectin extracts.

The spent plant raw material is typically used for cattle feed.

Isolation. Following filtration, the extract may optionally be passed through a column with cation-exchange resin and concentrated by evaporation. The pectin is then precipitated by mixing the extract with an appropriate alcohol, e.g., 2-propanol. Finally, the precipitate is separated from the spent alcohol, washed in more alcohol, pressed to drain as much liquid as possible, and then dried and milled. The powder is now ready for

standardization, i.e., mixing with other pectin batches and/or sucrose in order to ensure uniformity. The alcohol is recovered by distillation. An alternative to alcohol precipitation is precipitation by adding appropriate metal salts to the extract. Pectin forms insoluble salts with, e.g., Cu^{2+} and Al^{3+}. The Al^{3+} precipitation [125] was previously used industrially. Removal of the metal ions from the precipitated pectin is done by washing in acidified aqueous alcohol.

Modification. Pectin derived from citrus or apple raw material as described above will normally have a degree of esterification between 55 and 75. A lower degree of esterification can be achieved by acidifying the extract and leaving it for some time before precipitation, or by treating precipitated (but not dried) pectin with acid or alkali during suspension in aqueous alcohol. Ammonia may convert methyl-esterified carboxylate groups of a pectin to primary amides [42], [43]. This is done industrially by suspending precipitated pectin in a mixture of alcohol and water with dissolved ammonia [127], [128]. Deesterification takes place concurrently. By choosing proper conditions with respect to ammonia concentration, water activity, and temperature, pectins with various proportions of amidated, methyl esterified and free carboxylate groups can be produced.

Standardization. The properties of botanical raw materials like those used for pectin fluctuate due to, e.g., weather conditions or sorts variation. Pectin as it appears directly from milling contains this variation. In order to maintain a constant quality, the pectin manufacturer may mix different batches. Further, pectin intended for food is typically diluted with sucrose in order to achieve a uniform grade (i.e., “strength,” for a definition, see Section Measurement and Standardization of Gel-Forming Capacity). Pectin without admixed sugar, e.g., for pharmaceutical purposes, is also available from the major manufacturers.

Due to the multitude of ways in which pectins may vary, it is not possible to ensure batch to batch consistency with respect to all possible attributes at the same time. Pectin is normally standardized with respect to a few properties which are measured in defined chemical systems which simulate the applications, e.g., breaking strength of a gel, gelation temperature, etc. The major pectin manufacturers have developed a great number of specialty types which are tailor-made for individual applications and which have each their set of standardization criteria (control methods). In fact, a pectin type is defined by its set of standardization criteria. When using pectin, it is obviously important to choose a type which has been standardized in a way that corresponds reasonably to the intended use.

3.4. Properties

A range of parameters — intrinsic and extrinsic — are important for the performance of pectin which is in most cases used to impart certain rheological properties, e.g., by forming a gel. The *intrinsic parameters* determine the nature of the gel and may include molecular mass, degree of esterification (DE), degree of acetylation (DA), neutral sugar content, and composition. The *extrinsic parameters* which determine the gelation process may include pectin concentration, pH, ionic strength, water activity, and temperature.

The most important properties of pectin preparations depend on their molecular mass and DE and DA. The proportion and nature of neutral sugars in the side chains as well as in the “ballast” are also of significance. Pectin with a high degree of polymerization is more viscous in solution compared to a pectin with a lower degree of polymerization. Further, the gel strength will typically increase with the degree of polymerization, i.e., less pectin is needed with a high molecular mass pectin [44-46]. The DE strongly influences the functional properties of pectin with the two main groups, HM- and LM-pectin being influenced differently. At the typical conditions in HM-pectin applications, high DE means high gelling temperature whereas at typical use conditions for LM-pectins, low DE means high gelling temperature. No experimental evidence is available to demonstrate the influence of the hairy regions (see Structure.) on the functionality of pectin. It could be speculated that by being bulky and providing kinks in the molecular chain, these parts will prevent molecules from aligning throughout their entire length. This may contribute to preventing precipitation and reducing potential syneresis (spontaneous exudation of solvent from the gel).

Chemical Reactions. By treating pectin with ammonia under alkaline conditions in alcohol suspensions, ca. 20 % of the methyl ester groups are converted to acid amide groups, and amidated pectins are obtained [129]. Amidated pectins have a higher calcium reactivity than LM-pectins, and gels can be obtained with very few Ca^{2+} ions [134]. Carboxyl groups in pectin can be esterified easily with methanol [126], glycol, and glycerol but poorly with ethanol [135]. By using polyols, cross-linked, insoluble systems are obtained. Insoluble pectates can also be prepared by cross-linking with epichlorohydrin; these pectates have ion-exchange properties with a certain selectivity for calcium and heavy-metal ions. They are successfully used for the isolation of pectolytic enzymes [136], [137]. Pectins are readily degraded by oxidants [138] except for chlorite and chlorine dioxide, which can selectively oxidize aldehyde groups at the reducing chain end [139].

3.4.1. *Physical Properties*

Pectin is water-soluble, exhibiting an increased solubility with increasing DE and decreasing degree of polymerization. In order to ensure complete dissolution of pectin, it is necessary that it is properly dispersed without lumping. Once formed, lumps are extremely difficult to dissolve. Pectin, like any other gum or gelling agent, will not dissolve in media where gelling conditions exist. In order to add pectin to complex formulations such as food systems three alternative procedures are recommended: (1) dissolve the pectin in pure water and add the solution; (2) dry blend the pectin with five parts of sugar and add the mixture; (3) disperse the pectin in a liquid in which it is not soluble and add the dispersion.

Aqueous dilute pectin solutions, i.e., with a pectin content below 0.5 % are almost Newtonian whereas more concentrated pectin solutions exhibit pseudoplasticity, i.e., shear-thinning behavior. From dilute viscosity data, the intrinsic viscosity, $[\eta]$ (dL/g) may be determined. $[\eta]$ indicates the hydrodynamic volume of a polymer molecule and depends primarily on the molecular mass, however viscosity is also influenced in a complex manner by many other factors such as the DE, pH (dissociation), and ionic strength. $[\eta]$-values for pectins typically lie in the range of 1.0 to 6.0 dL/g [47-51]. The molecular mass of pectin is often estimated by intrinsic viscosity methods using the Mark – Houwink relationship $[\eta] = KM^{\alpha}$ (see Section Analysis). Originally an α-value of 1.34 [52] was suggested corresponding to a rigid rod-like molecular structure, however more recent findings estimate α to be in the range 0.7 – 0.8 indicating a random coil structure [47], [49], [53], [54].

Pectin is insoluble in most organic solvents such as alcohols and acetone. Pectin can also be precipitated from aqueous solutions by quaternary detergents, water-soluble cationic polymers including proteins, and multivalent cations. LM-pectins can be precipitated by calcium ions; pectates by alkali cations and by acid.

Pectin is a polycarboxylic acid. Dissolved pectin is negatively charged at neutral pH and approaches zero charge at low pH. Since pectin is a polyprotic acid it is not possible to determine an exact value of the apparent dissociation constant, pK_a. Rather, pK_a is different for varying carbohydrate concentrations and for varying degree of dissociation, α. The negative charge density, in turn, is dependent on DE which implies that pK_a-values are increasing with increasing content of unesterified galacturonic acid units. Typically, pK_a-values at 50 % dissociation, i.e., $\alpha = 0.5$, lie in the range 3.5 – 4.5 [55-59]. The usual dependence of pK_a with polymer concentration and ionic strength is observed, i.e., pK_a is lowered with increasing concentration and ionic strength.

3.4.2. *Gel Properties*

Pectin is used mainly as a gelling agent in industry; therefore its gelling properties are most important [4], [6], [106], [117]. The gel formation mechanism of pectin is similar to that of other gelling polysaccharides: Some regions of the polymer molecules associate in junction zones to form a three-dimensional network, which traps the solvent with cosolutes; free stretches of the molecules provide elasticity to the gel obtained [111], [140], [141] (Fig. 6). Irregularities in the pectin molecule, such as the distribution pattern of methyl ester or *O*-acetyl groups, rhamnosyl residues in the backbone, or the presence of side chains, limit the length of the junction zones and give shape to the free stretches of the macromolecules [142].

Figure 6. Network of a gel

A comprehensive, coherent description of pectin gelation does not exist. Conventionally, a distinction is made between HM- and LM-pectin gelation, however, in reality this paradigm is too simple. It applies that different gelation mechanisms may act simultaneously. This is e.g., illustrated by the fact that gelation of LM-pectin, which is normally claimed to gel in the presence of certain metal ions, is further favored by a decrease in pH. If the gelation was solely determined by the formation of calcium-bridges between molecules, the opposite effect would be expected, an increase in pH leading to an increase in gel strength.

In order to adapt the conventional and still widely accepted theories for pectin gelation, the gelation phenomenon will, however, be treated as two distinct mechanisms, ie HM- and LM-pectin gelation. Gels used for jams and jellies are typically formed with HM-pectin at an acidic pH and require the presence of a high concentration of sugar. LM-pectin is typically used for yogurt fruit preparations; these gels can be formed without sugar over a wide pH range, however, the presence of a divalent cation is necessary. In most cases the cation, i.e., calcium, is inherently present in the fruit material. LM-pectin gels can be remelted whereas usually it is not possible to melt an HM-pectin gel, i.e., with HM-pectin gel preparations, the difference between the apparent temperatures of setting and melting is so large that the gels are said to be thermo-irreversible. Further, LM-pectin gels solidify almost immediately after gelling conditions have been introduced, while an HM-pectin gel will build up over time.

HM-pectins form so-called *low-water-activity* or *pectin – sugar – acid gels* and are used in jam, jelly, and marmalade production. The basic galacturonan chain (smooth regions) of the pectin molecule apparently contains blocks with conformational regularity to provide opportunities to build up junction zones. The homogalacturonan part of the molecule is configured as helices with three anhydrogalacturonic acid units per turn, with the methyl ester groups protruding from the helix. According to OAKENFULL and SCOTT [143], junction zones are stabilized by different forces between pectin chain molecules: hydrogen bonds between undissociated carboxyl and secondary alcohol groups, and hydrophobic interactions between methoxyl groups (Fig. 7). Both types of forces are fortified by sucrose; the low pH suppresses the dissociation of carboxyl groups. Sugar reduces the water activity of the system and thereby influences hydrogen bonding by decreasing polymer – water interactions and increasing polymer – polymer interactions. To a certain extent, sugar and acid are interchangeable: at lower sugar concentration, lower pH is required, but at higher sugar concentration, higher pH values are possible and necessary to avoid setting during the boil. The lower limit for the sugar concentration is 55 %. At this concentration, the pH should not be higher than 2.8. At a sugar concentration of 80 % (jellies), the mass will also gel at pH 3.5. This means that within the gelling range, at the same sugar concentration, more acid will give a stronger gel and, at the same pH value, this is achieved by adding more sugar. Addition of urea to a gel cancels out hydrogen bonds and results in a weaker gel with a lower setting temperature [144].

Figure 7. A) Junction zone in high ester pectin gel by hydrogen bonds (dotted lines) and hydrophobic interactions (filled circles); B) Junction zone in low ester pectin gel by dimerization of polygalacturonate (polyguluronate blocks) induced by their strong binding power for Ca^{2+} ions which fill the oxygen-lined cavities between the polysaccharide chains [110]

In general, pectin – sugar – acid gels are prepared by a boiling process followed by cooling. At a certain temperature the system sets to a gel. The food technologist is interested in the rate of setting. At the same rate of cooling the rate of setting determines the setting temperature or the setting time. The parameters that contribute to stronger gels also accelerate the setting rate. Based on the pH limits of gelling as well as on the setting rate, HM-pectins can be subdivided into rapid-set (DM > 70 %) and slow-set (DM 60 – 65 %) pectins. At the same sugar concentration, rapid-set pectins have a higher pH limit for gelling because these very highly methyl esterifiedpectins have few carboxyl groups that must be protonated. A fully methyl esterified pectin gels with sugar alone and does not need acid. The concentration of pectin in the gel influences the rheological properties of the gel, not the gelling rate.

LM-pectins form so-called *calcium pectate gels.* Theories about the chemical structure of calcium pectate gel junction zones were first developed in comparison with alginate gels (see Chapter Alginates). In calcium alginate gels, the junction zones are formed by α-1,4-L-polyguluronate blocks in which the diaxial configuration of the glycosidic linkages leads to a buckled ribbon with limited flexibility and a strong binding power for Ca^{2+} ions, which induce dimerization of alginate chains by filling the oxygen-lined cavities between them. This has evoked the picture of an eggbox, and the expression eggbox-type junction zones has become universally accepted [111], [141], [145], [146] (Fig. 7). In comparing the primary structures of poly-L-guluronate and poly-D-galacturonate (pectin), they are seen to be stereochemically analogous mirror images of each other, except at C-3. The two-fold helix, however, has not been observed with X-ray diffraction techniques, but molecular modeling calculations indicate that it can exist [60]. Circular dichroism data [61] suggest that a conformational change takes place when dissolved or Ca^{2+}-gelled pectate is dried and it is suggested that a transition takes place from a 2_1 ribbon-like to a 3_1 helical symmetry. Similar to the low-water-activity gels, junction zones in calcium pectate gels are terminated by rhamnosyl residues in the backbone, side chains attached to the backbone, or acetyl groups. The presence of some methoxyl groups does not inhibit formation of eggbox-type junction zones. With LM-pectins, acids or sugars are not so important. Gels of acidic fruit juices with LM-pectins can be made by addition of a calcium salt (low-sugar jams) or of milk with its neutral pH and calcium ions (desserts). The amount of calcium necessary for gelation depends on the degree of esterification, the way the LM-pectin has been prepared, and the types and amounts of other ingredients. Coagulation as a result of the addition of calcium salts must be absolutely avoided. Slow availability of Ca^{2+} for the pectin molecules is a prerequisite for obtaining a gel network. This can be accomplished in various ways: (1) an insoluble calcium salt (phosphate, citrate, tartrate) may be used resulting in a slow exchange of Ca^{2+} ions with the LM-pectin and formation of a gel; (2) use of calcium chelating agents such as diphosphates help to retard the availability of Ca^{2+} ions. The fact that calcium pectate gels and precipitates are often thermoreversible (i.e., they are soluble under conditions of gel formation at high temperature) can also be used to advantage. Soluble calcium salts such as calcium lactate or calcium chloride can therefore be added at boiling temperature, and gelling occurs on cooling. LM-pectins can be solubilized in milk by heating; the calcium caseinate of the milk provides the calcium necessary for the system to gel on cooling. Addition of sugars to such gels gives stronger gels; however, at higher concentrations the risk of coagulation increases. A solution to this problem is offered by *amidated pectins*. Gel formation with amidated pectins is also explained by chain associations via eggbox junction zones. Eggbox junction zones can accommodate amide groups, which, however, provide less drive for Ca^{2+} ion binding [146], [147]. On the one hand, they need fewer Ca^{2+} ions for gelation, and on the other hand in the presence of excess Ca^{2+} ions they are not as sensitive to coagulation [148]. In the United States, amidated LM-pectin is used for all applications of LM-pectins.

3.4.3. *Stability and Chemical Reactions*

Stability of pectin molecules in aqueous solution depends upon the temperature and the pH. Pectin has, in contrast to most other hydrocolloids, optimal stability at pH 3.5 to 4. Figure 8 shows the stability of pectin and some other thickening agents at various pH values, expressed as residual viscosity of buffered solutions after heating for 10 min at 90 °C [131]. As is evident from the figure, highly esterified pectin is vulnerable to high pH. Even at pH 5, depolymerization is considerable, in particular at elevated temperatures [133]. Consequently, it is difficult to raise the pH of pectin solutions without causing a decline in the average degree of polymerization, because when trying to mix an alkaline solution into a pectin solution, too high pH cannot be avoided locally. It is recommended to ensure good agitation and low temperature, and to avoid the use of hydroxides.

Figure 8. Stability of some polysaccharides at various pHs [131]: Residual viscosity after 10 min incubation at 90 °C

a) Carboxymethylcellulose – methyl cellulose; b) Locust bean gum; c) Agar; d) Carrageenan; e) Pectate; f) Pectin

Low pH hydrolyzes ester bonds causing a decline in DE as well as in the content of *O*-acetyl groups, and it causes a decline in degree of polymerization by hydrolysis of glycosidic bonds [64], in particular at rhamnose insertions in the molecular backbone [65]. Very high acid concentration may degrade galacturonic acid to CO_2, furfural, reductic acid (2,3-dihydroxy-2-cyclopenten-1-one; $C_5H_6O_3$) and alginetin. Carbon dioxide production which is quantitative by boiling in 12 mol/L HCl has in the past been used for the quantitative determination of pectin [85], [132].

High pH depolymerization is due to β-elimination [66] (Fig. 9), it requires the presence of a methyl ester group at the anhydrogalacturonic acid residue which has its 4-C attached to the bond being split. Since the presence of methyl esters is required for β-elimination, vulnerability to this degradation mechanism is related to the DE. High pH further reduces DE (whereby the β-elimination becomes incomplete) as well as the content of *O*-acetyl groups.

Figure 9. β-Eliminative depolymerization of a galacturonan chain by pectin lyase (PL) or pectate lyase (PAL) or chemically at pH ≥ 5

Derivatization. The low-pH hydrolysis of natural ester linkages may be reversed under conditions of low water activity, e.g., in mixtures of methanol and concentrated sulfuric acid [67], [68], [126], or, for introduction of *O*-acetyl groups, mixtures of concentrated sulfuric acid and acetic anhydride [69]. Further, the carboxyl group may readily be esterified with glycol or glycerol but poorly with ethanol [135]. By using polyols, cross-linked, insoluble systems are obtained.

At high pH, ammonia may convert methyl esterified carboxylate groups to amides [42], [129]. This is used industrially since amidated pectins are of commercial importance.

Insoluble pectates can be prepared by cross-linking with epichlorohydrin; these pectates have ion-exchange properties with a certain selectivity for calcium and heavy-metal ions. They are successfully used for the isolation of pectolytic enzymes [136], [137].

Pectins are readily degraded by oxidants [138] except for chlorite and chlorine dioxide which can selectively oxidize aldehyde groups at the reducing chain end [139].

3.5. Analysis

3.5.1. *Measurement and Standardization of Gel-Forming Capacity*

HM-pectins are generally standardized to uniform strength at specified constant conditions. Expressing the sugar binding capacity of the pectin, the USA – SAG method suggested by the IFT Committee for Pectin Standardization, has been universally accepted for grading HM-pectins [149]. A standard gel is prepared in conical test glasses with the following conditions: soluble solids 65 %, pH 2.20 – 2.40, gel strength 23.5 %, SAG measured with a *ridgelimeter* [106], [153]. After 24 h at 25 ± 3 °C the gel is deposited on a glass plate, and the sagging of the gel under its own weight is measured after 2 min. From the SAG value and the pectin quantity, the grade can be calculated. Most commercial HM-pectins are standardized to 150 grade USA – SAG. (A gel strength of 150 grade SAG implies that 1 part of pectin is able to transform 150 parts of sucrose into a jelly with above standard properties.)

LM-pectin may be standardized by closely analogous procedures, however, no universally accepted method exists. With LM-pectins it is difficult to set up a single universal test because the conditions under which LM-pectins are used may differ widely with respect to soluble solids, calcium content, and pH (see also Standardization.).

3.5.2. *Chemical Analysis [70]*

In addition to gel-forming ability, the analysis of pectin preparations is concerned particularly with the *degree of of esterification, DE*. This is determined by converting the pectin to its acid form by passing it over an ion-exchange resin or washing it in an alcohol suspension, first with hydrochloric acid – alcohol and then with neutral alcohol. The acid and saponification equivalent is determined by titration, and from these values the anhydrogalacturonic acid content and the DE (in percent) can be calculated [63]. This principle for determination of DE has been adopted by the major legislative bodies [71-73]. Presence of *O*-acetyl groups in the pectin will result in an overestimation of DE as well as the anhydrogalacturonic acid content, therefore, it should be evaluated in a separate aliquot of the preparation. The pectin can also be precipitated with copper ions before and after saponification to determine the copper in the well-washed precipitate. From the amount of copper ions bound to the original pectin and the saponified pectin the anhydrogalacturonic acid and the DM can then be calculated without the interference of acetyl groups [151], [152]. Various methods exist for the separate determination of methyl ester and acetyl groups. Methanol is released on saponification of methyl ester and can be determined by GLC either directly [153] or in the headspace of a closed vial after conversion of the methanol to volatile methyl nitrite [154], [155]. *Acetyl groups* can be conveniently determined by an enzymatic spectrophotometric method (supplier Boehringer), by GLC [156], or by distillation and titration after alkaline saponification [157]. A convenient new method is to saponify the pectin preparation in alkaline alcohol, which is then analyzed by HPLC for methanol and acetic acid [158]. Methods measuring the relative content of carboxylate groups to total material, either using size exclusion chromatography with combined detection by conductivity and refractive index [75], or using capillary electrophoresis [76], have also been published. The DE can be inferred from calibration curves if it can be assumed that the anhydrogalacturonic acid content is the same in the samples compared. Previously, the analytical methods used by legislative bodies did not comprise a correction for *O*-acetyl groups since the content of those is small in citrus pectin and modest in apple pectin, but it has now been included in the latest version of the FAO/WHO specification for pectin [71].

In commerical pectins, up to 25 % of the carboxyl groups may be amidated. The *degree of amidation* is calculated from the amount of ammonia released on alkaline distillation [63], [159]. Amidated pectic acids undergo β-elimination reactions, whereas pectic acid does not, which permits quantitative analysis of mixtures of amidated and nonamidated pectins [160]. The anhydrogalacturonide content of pectins can also be determined from aqueous solutions by colorimetric methods with carbazole [161], the more specific *m*-hydroxydiphenyl [162], or sulfamate – *m*-hydroxydiphenyl [163]. Sometimes corrections must be made for interfering compounds (neutral sugars, amide groups, azide). The colorimetric methods can be automated easily and used for routine analyses of large series of samples [130].

With the above-mentioned methods, only the galacturonide residues in the backbone can be analyzed. The *neutral sugars* can be analyzed conveniently by gas chromatography after acid hydrolysis and conversion to volatile derivatives. By a preceding precipitation of pectins with copper

ions the neutral sugars covalently attached to the galacturonan can be analyzed specifically. If starch is present it can be removed by enzymatic degradation [164].

To analyze the *pectin of plant material* the so-called alcohol-insoluble residue is usually prepared first by washing the plant material with refluxing alcohol. This inactivates endogenous enzymes and removes alcohol-soluble constituents. The pectin content is then determined in extracts of the alcohol-insoluble residue. The total pectin is determined in an alkaline extract or in the combined extracts of enzymatic and acid extraction. Another approach is the gradual extraction first with cold or hot water (HM-pectin), oxalate, ethylenediaminetetraacetic acid (EDTA), or cyclohexanediamine tetraacetate (CyDTA) (LM-pectin), and then acid or alkali (protopectin) [165], [166]. The total pectin content and the average degree of methoxylation can also be determined in the alcohol-insoluble residue when this is converted to the acid form before and after saponification. When treated with alcoholic calcium acetate solutions, the free carboxyl groups of pectin set free an equivalent amount of acetic acid that can be determined by titration. An alternative is determination of the bound copper ions from copper solutions [151].

Molecular mass of pectin may be determined with viscosimetry [44], [77], membrane osmometry [78], size exclusion chromatography [47], [48], [54], light scattering [54], [77], [79], [80], ultracentrifugation [34], and analysis of reducing end-groups [80]. Quoted results vary, partly because the intermolecular distribution of molecular mass is broad, partly because pectin molecules aggregate and may contain slight amounts of insoluble material, and, of course, partly because samples are different. As an example, a weight average molecular mass of 90 000 ± 10 000 was reported by HARDING et al. [34]. Quoted values for the Mark – Houwink exponent, relating intrinsic viscosity to molecular mass, are generally in the vicinity of 0.8 [47], [49], [53], [54], suggesting a random coil molecular shape. Integrated systems combining high performance size exclusion chromatography, viscosity detection and light scattering detection are commercially available, including software with which data for molecular mass and Mark – Houwink parameters can be extracted.

3.6. Pharmaceutical and Nutritional Characteristics [167]

Pectin is not significantly degraded in the upper digestive tract of humans, and it can be recovered almost intact from the small intestine [81]. In the cecum and colon, it is fermented by microorganisms mainly to short-chain fatty acids, as can be concluded from in vitro studies [82], rat studies [83] and studies comparing the degradation patterns of humans and rats [84]. Since pectin is a dietary fiber, much attention has been paid to the possible health benefits of pectin which are: (1) reduced glycemic response [86-88], (2) prolonged gastric residence time [89-91], (3) reduced serum cholesterol level [86], and (4) effect against diarrhoea [92]. Pectic polysaccharides from certain botanical sources like ginseng root (*Panax ginseng*) [93], eel grass (*Zosteraceae*), and *Bupleurum falcatum* [94], [95] have shown healing effect on gastric and duodenal ulcers. Most studies, e.g., [97-99], conclude that pectin, in spite of its metal-binding ability, apparently does not inhibit the uptake of minerals from the diet. All of the above effects must be thought of as general tendencies in a vast amount of published findings which are not all mutually consistent. Some discrepancies may be explicable because it is attempted to generalize results achieved with different systems (in vitro, animal, or human) and with different pectins or pectin-rich plant materials. Publications often fail to specify important details about the pectin being used for the study, such as botanical origin, DE, etc.

3.7. Application in the Food Industry [168]

Indigenous manufacture of jams and marmalades, before commercial stabilizers were available, involved the use of pectin-rich fruit and in situ extraction of the pectin during prolonged cooking. Partly owing to this tradition, but mostly due to its superior stability and gelling ability at relatively low pH, pectin is the dominating gelling agent in modern production of jams as well as other products which are gelled, acidulous, and sweet. Examples are jelly fruits, and fruit preparations for industrial production of fruit-containing yogurt (Table 2 groups 1 and 2). Commercial pectins for these applications are tailor-made to yield specific gelation temperatures or gelling rates under specified conditions, and to exhibit specific functionalities such as heat reversibility, heat resistance, firmly gelled textures, pumpable semi-gelled textures, etc. *HM pectin* is used as a stabilizer in yogurt beverages and beverages in which milk proteins are heat-treated at relatively low pH during the production [100-102]. LM pectin finds use for thickening spoonable yogurt (Table 2 group 6). Particles of calcium pectinate are used as a substitute for fat in low-calorie foods [103] (Table 2 group 12). Other applications from Table 2 include groups 4, 8, 9, 10, and 11.

3.8. Market

Annual pectin production is estimated at 25 000 t (80 % citrus pectin), sold mostly in standardized form. Pectin production takes place in Brazil, Denmark, France, Germany, Mexico, Switzerland, and United Kingdom. Smaller amounts are produced in Eastern Europe and the former Soviet Union. Average prices on the world market are $10 – 11 per kilogram HM-pectin and $ 12 – 13 per kilogram LM-pectin.

[Top of Page]

4. Alginates

Alphons C. J. Voragen and Ian Challen

Alginate is a collective term for a family of linear 1,4-linked α-L-gulurono- β-D-mannuronans of widely varying composition and sequential structures [169]. Commercial preparations are usually designated as alginates and include alginic acid, its salts, and derivatives [2], [3], [5], [170-175].

4.1. Occurrence

Alginates form a group of polysaccharides that occur as structural components of the cell walls of brown seaweed (Phaeophyceae; Fig. 10) in which they make up to 40 % of the total dry matter and play an essential role in maintaining the structure of the algal tissue. They were isolated for the first time in 1880 by STANFORD [176], who also introduced the names algin for the soluble substances in an aqueous sodium carbonate extract and alginic acid for the material that could be precipitated from this extract by addition of acid.

Figure 10. Origin of seaweed extracts — general classification

[a] Species of economic significance; [b] Contains only component mentioned; [c] Contains predominantly underlined component

The brown weeds occur in many parts of the world. For example, on the west coast of North America the giant kelp *Macrocystis pyrifera* is harvested mechanically by special ships, which cut the weeds at a depth of 1 m. The weeds grow so fast that they can be harvested several times a year. Other species are harvested semi-mechanically by fishing boats, collected by reaping hooks, harvested from shore at low tide, or collected directly from the beach. Many regions have a tradition of harvesting or collecting brown seaweed, which in the past was used for the extraction of iodine and sodium carbonate.

4.2. Production

Various brown seaweed species are used as raw materials to obtain a range of specific properties (Table 3).

Table 3. Species of brown seaweeds (Phaeophyceae); alginate content and ratio between mannuronic and guluronic acid residues (data from various sources [283])

Species	% Alginate DM *	Man : Gul
Macrocystis pyrifera	13 – 24	1.4 – 1.8
Ascophyllum nodosum	20 – 30	1.4 – 1.9
Laminaria digitata	15 – 27	1.3 – 1.6
Laminaria hyperborea (leaf)	15 – 26	1.3 – 6.0
(stem)	27 – 33	0.4 – 1.0
Ecklonia maxima	30 – 38	1.4 – 1.8

	Mannuronan	Guluronan	Alternating
Macrocystis pyrifera	40.6 %	17.7 %	41.7 %
Ascophyllum nodosum	38.4 %	20.7 %	41.0 %
Laminaria hyperborea	12.7 %	60.5 %	26.8 %
Azetobacter vinelandii (acetylated)	17.8 %	0.5 %	81.7 %

* DM = Dry matter.

The production of alginates is shown schematically in Figure 11. Current processes are still based on patents that were filed in the 1930s by U.S. companies [185], [186]. Alginate production is based on a series of ion-exchange processes: The water-insoluble calcium alginate in the raw material is, for the purpose of extraction and purification, converted first to the soluble sodium form and then, possibly via the calcium form, to insoluble alginic acid, which is neutralized to obtain the finished product.

Figure 11. Flow sheet for the production of sodium alginate [171]

While the *Macrocystis* is taken to the processing factory directly by boat other species are air dried before being transported for processing. The weeds are dried mechanically, ground, and then transported to factories. Salts, which might influence the solubility, and other impurities such as the high-polymeric laminarin (a β-1,3; β-1,6-D-glucan) are removed by washing. The alginate remains in an insoluble form as the calcium salt or as alginic acid. Extraction of the material with cold or hot soda follows, combined with a mechanical disintegration. A homogeneous mass with a pH of ca. 10 – 11 is obtained. After dilution with water, the slurry separates into a liquid phase (sodium alginate) and a solid phase consisting predominantly of cellulose. For removal of these solid impurities, a flotation step may precede the classical separation processes such as sieving and filtration. Alginic acid is obtained from purified sodium alginate by direct precipitation with acid or by precipitation with Ca^{2+} as calcium alginate and subsequent conversion to alginic acid by washing with acid. For the destruction of chloroplasts, either the sodium alginate solution or the calcium alginate precipitate is bleached with hypochlorite. Washed and mechanically dewatered alginic acid can be dried as such; in general, however, it is treated with sodium carbonate or other bases to produce alginate salts. The finished products are highly refined, odorless white powders, which are permitted as food additives. For industrial purposes, less purified preparations are often sufficient.

4.3. Structure

Until 1954, alginate was considered to be composed of polymannuronic acid. In 1955, FISCHER and DÖRFEL [177] discovered L-guluronic acid in addition to D-mannuronic acid, and since ca. 1964, alginic acid has been known to be a copolymer of these two residues. In principle, alginates are composed of three structural elements: the homopolysaccharides α-1,4-L-guluronan and β-1,4-D-mannuronan, and a heteropolysaccharide consisting of alternating 1,4-linked α-L-guluronic (G) and β-D-mannuronic acid (M) residues [178] (Fig. 12). The structure of alginate can therefore be represented schematically as

$$– M – G – M – (M – M)_n – M – G – (M – G)_q – M – G – (G – G)_p – G – M – G –$$

Figure 12. Structural units in alginates

Alginates, like pectins, are linear polymers. The D-mannuronic acid residues are in the $^4C_1$ configuration, and therefore the glycosidic linkage between them is equatorial – equatorial. Since the L-guluronic acid residues are in the $^1C_4$ configuration, they are connected by axial – axial glycosidic linkages similar to the linkages between galacturonosyl residues in pectin. However, unlike pectin, alginates do not contain neutral sugar residues. The properties of alginates are determined largely by their molecular mass and by the ratio in which the three structural elements occur in the polymer. This ratio is determined by the variety of seaweed from which the alginate is extracted [172], [175], [179-182].

The *biosynthesis in plants* starts from D-mannose which, via guanosine diphosphate mannose, is oxidized to guanosine diphosphate mannuronic acid by a NAD dehydrogenase system and then polymerized to polymannuronic acid by a transferase enzyme. In homogenates of brown seaweed, guanosine diphosphate guluronic acid has also been identified, so at the end of the pathway copolymerization may also occur [173].

4.4. Properties [188]

Solubility. *Alginic acid* itself is insoluble in water and precipitates at pH < 3.5. The ammonium, alkali and magnesium salts, and alginate salts with

organic bases are water soluble; calcium ions and other multivalent ions precipitate with alginates. *Alginates* are insoluble in organic solvents and can be precipitated with alcohols. They are, however, slightly miscible with simple alcohols, glycerol, and glycols, and these compounds can therefore be included to a certain content in alginate solutions. The dissociation constant p*K* of monomeric mannuronic acid is 3.38, and of guluronic acid 3.65. Alginic acid with a high proportion of guluronan has a p*K* of 3.74, when the proportion of mannuronan is high, this value is 3.42.

Degree of Polymerization. The properties of alginates depend largely on the degree of polymerization and the ratio of guluronan : mannuronan blocks in the molecules. The mannuronan regions in the molecules with their diequatorial glycosidic linkages are stretched and flat, while the diaxial glycosidic linkages in the guluronan regions give this part of the alginate molecule a buckled ribbon shape with limited flexibility.

Viscosity. The high viscosity of aqueous alginate solutions is a function of the degree of polymerization and is one of their most important properties (Table 4).

Table 4. Dynamic viscosities (in mPa · s) of polysaccharide solutions at different concentrations (data from various sources [283], [41], [62], [63]) *

Concentration	Pectin	Alginate	Carrageenan	Agar	Gum arabic	Gum tragacanth	Gum karaya	Gum ghatti	Xanthan	Locust bean gum	Guar gum
1 %	50	214	57	4		54	3 000	6	2 000	59	3 025
2 %	200	3 760	397	25		906	8 500	10	7 000	1 114	25 060
3 %	550	29 400	4 411			10 605	20 000	40	11 500	8 260	111 150
4 %		39 660	25 356	400		440 265	30 000	60		39 660	302 500
5 %			51 425		7	111 000	45 000			121 000	510 000
10 %					17						
30 %					200						
50 %					4 163						

* Reported value give only general trends. Depending on preparation and measuring conditions differences may occur.

By mixing alginates of different sources, and by oxidative degradation, manufacturers can offer products with viscosities varying from 4 – 1000 mPa · s for a 1 % solution. Viscosity numbers alone are meaningless without the shear stress or shear rate because alginate solutions are Newtonian fluids only at very low shear rates and low concentrations. Under other conditions, they are pseudoplastic. Table 4 also shows the strong concentration dependence of viscosity. Cations have a significant effect on viscosity. Low concentrations of Ca^{2+} ions considerably increase the viscosity as a result of complex formation. In measuring the viscosity of alginate solutions a distinction is made between the “direct” viscosity and the “sequestered” viscosity. The latter is always lower because a sequestrant removes the Ca^{2+} ions.

Effect of Shear. In common with most other food hydrocolloids, sodium alginate solutions are pseudoplastic. In solution the alginate molecule is long, thin, and rigid. When the solution is at rest, the alginate molecules interfere with each other forming loose entanglements. When shear is applied to the solution, the molecules are oriented in the direction of the shearing force. The association between the molecules is greatly reduced and there are no longer any entanglements. The result is an immediate lowering of the viscosity. When the shear is removed, the molecules entangle again resulting in the recovery of the viscosity.

Effect of pH. Between about pH 4.5 and 10, there is little change in solution viscosity. At about pH 3.8 the solution viscosity increases dramatically and, as the pH is reduced further the alginate is precipitated out of solution as alginic acid. At higher pHs viscosity is lost by a β-elimination process. The glycosidic linkages between mannuronic and guluronic acid residues are known to be less stable to acid hydrolysis than the linkages between two mannuronic or two guluronic acid residues [190]. The homopolymers are slightly more stable than heteropolymers.

Effect of Sequestrants. Sequestrants are used with alginates to soften the water so that the alginate can hydrate completely and thus modify the rate of the calcium – alginate reaction. They may also be used to sequester the calcium ions naturally present in the alginate itself. Different sequestrants bind different amounts of calcium ions at different pHs. Therefore, it is important to understand which sequestrant is being used and at what pH it will be used at.

Effect of Salts. The presence of *monovalent salts* reduce the viscosity of sodium alginate solutions. The viscosity drop occurs because alginates, in common with other polyelectrolytes, contract as the ionic strength increases.

As *polyvalent cations*, usually calcium ions, are gradually introduced into a sodium alginate solution, they cause the alginate polymer chains to start to align — this is seen as an increase in the solution viscosity. As more calcium is added the solution viscosity increases further to a point where there is evidence of some gel structure. At this stage, the solution shows thixotropic properties — the viscosity decreases when sheared, pumped, or shaken but the structure is regained when the shear is removed. Higher levels of calcium ions result in coherent gel formation. Typically, this occurs when more than about 70 % of the alginate has been converted into the calcium alginate form. The introduction of even more calcium ions increases the strength of the gel until, finally, all of the alginate is precipitated out of solution. At this stage all solution viscosity is lost.

Gel Properties. In food applications, sodium alginates are used as gelling agents, which in many aspects resemble LM-pectins and also form gels with Ca^{2+} ions. As pure polyuronic acids, alginates are, however, more sensitive to acid than pectins and are insoluble at pH < 3.5. Alginates also have a higher sensitivity to calcium than pectins, which is probably due to their higher degree of polymerization. For the preparation of acid gels, calcium salts are used that are soluble only under acidic conditions, together with compounds that release H^+ ions slowly, for instance, slowly soluble fumaric acid or slowly hydrolyzing glucono-1,5-lactone. The use of sequestrants has also been mentioned. The gel-forming ability of alginates is related mainly to the proportion of L-guluronan blocks. These blocks bind with Ca^{2+} ions according to a cooperative mechanism, giving rise to the formation of junction zones, which are referred to as the eggbox model (see Section Physical Properties). The junction zones in alginate gels are stronger than those in LM-pectin gels, and they are not thermally reversible even in the presence of sugar. Alginates rich in guluronan blocks form strong, brittle gels with a tendency to syneresis, whereas alginates rich in mannuronic acid form weaker more elastic gels that are less prone to syneresis [193]. Single mannuronic acid residues or mannuronan blocks interrupt the guluronan junction zones. *Propylene glycol alginates* form weaker gels. They can be prepared more easily because propylene glycol alginate is less sensitive to acid and Ca^{2+} ions and, therefore, less liable to coagulation. Alginates also gel in the presence of equimolar quantities of an HM-pectin. The strongest gels are obtained with HM-pectin and alginates with a high proportion of guluronic acid residues at low pH and in the absence of calcium ions. Sugar is not essential for gelation; but it does affect the gel properties [144], [194], [195].

Oxidation and Degradation. By using high acid concentrations and high temperatures, alginates and alginate esters can be quantitatively decarboxylated. Oxidants such as halogens or periodate, and redox systems such as polyphenols, ascorbic acid, or thiols, are able to depolymerize alginates. For production of low viscosity alginates, hydrogen peroxide is used. Bacterial alginate depolymerases have also been described [173],

[191]. These enzymes have been used to study the distribution of L-guluronic and D-mannuronic residues along the backbone. They have no commercial significance; however, they condition the chemical conservation of alginate solutions. The degree of polymerization of commercial alginates is in the range of ca. 80 to ca. 800.

4.5. Propylene Glycol (Propane-1,2-diol) Alginate

Propylene glycol alginate (pga) is prepared by treating partially neutralized alginic acid with propylene oxide [187] (Fig. 13).

Figure 13. Propylene glycol mannuronate unit

Pga's are completely soluble in both hot and cold water at neutral pH. Depending on the degree of esterification, pga can be water soluble at a pH as low as 2.5. As with the soluble alginate salts, the viscosity of a pga solution is a function of the degree of polymerization. Typically, pgas are available in the viscosity range 25 to 500 mPa · s for a 1 % solution and degrees of esterification from about 50 % to about 90 %. Highly esterified products cannot be made with highly polymerized alginates due to steric hindrance.

The flow properties of pga solutions depend upon the gum concentration and the shear rate: at high concentrations (e.g., > 1 %) they are shear thinning over a wide range of shear rates. At low concentrations they exhibit long, smooth flowing characteristics.

With increasing temperature the viscosity – shear rate curves are approximately linear over a wide range of shear rates and show progressively less pseudoplasticity with increasing temperature. This effect is reversed on cooling.

The bulky propylene glycol groups are responsible for the other different properties of the molecule. They physically hinder the aggregation of the polymer chains and also afford protection to the β,1–4 linkages. As a consequence of esterification, fewer carboxyl groups are available for interaction with divalent metal cations such as calcium. Propylene glycol alginates with less than 60 % esterification will react with calcium ions to give enhanced viscosity — such solutions are thixotropic but there is no evidence of gel formation or precipitation. Highly esterified pgas are not affected by the presence of calcium ions.

Propylene glycol alginates are tolerant to ionic materials such as salt and acid. The property of salt tolerance is made use of in barbecue sauces, salad dressings, and other liquid products. The esterification process reduces the ionic character of the pga molecule, thereby increasing its tolerance to low pH. The higher the degree of esterification the more tolerant the pga is to lower pH, but in strong acid the alginate chains depolymerize, with a resultant loss of viscosity [171].

In acid solutions proteins behave as bases and can interact with pga. This leads to some thickening and a degree of solution thixotropy, i.e., the solution exhibits high viscosity at rest but low viscosity when shear is applied. This property is used in meringues, cakes, and in the stabilization of beer foam.

The lipophilic ester side chains interact with fatty substances. Propylene glycol alginates build a molecular film around oil droplets thereby enhancing emulsification by inhibiting coalescence and droplet growth. Thus pgas provide dual functionality — they act as emulsifiers and show other rheological benefits. This film-forming property is also reflected in pga's abiltiy to form stable foams in aqueous solution. Thus, they are useful in protein-containing systems such as marshmallows and the stabilization of beer foam.

Legal Aspects. The *safety* of pga was evaluated by the Joint FAD/WHO Expert Committee on Food Additives (JECFA) in 1971, when it was assigned an Acceptable Daily Intake (ADI) of 0.25 mg per kilogram body weight. Pga has been an EC-approved food additive for over 25 years. It is listed as E405, in the Emulsifiers, Stabilisers, Thickeners and Gelling Agents Directive, 74/329/EEC.

4.6. Bacterial Alginates

Alginate production has also been reported in bacteria (i.e., *Pseudomonas aeruginosa* (pathogenic), *P. mendocina, P. putida, P. fluorescens*, and *Azetobacter vinelandii*). These alginates are also formed of the same three structural elements and are further characterized by the presence of *O*-acetyl groups. For *A. vinelandii* it has been shown that polymannuronic acid is synthesized first; mannuronic acid residues can then be transformed to guluronic acid residues by a mannuronan C-5 epimerase. With this enzyme both bacterial and algal alginates can be epimerized. The activity of the enzyme depends strongly on the Ca^{2+} concentration [169], [183], [184].

4.7. Analysis

The alginate content in alginate preparations can be determined by titration as described for pectins. From this analysis the degree of esterification can be deduced if propylene glycol alginate is present. In mixtures or foods, the uronic acid content can be determined by the colorimetric methods used for pectins [162]. If necessary this analysis can be preceded by a purification step. Titration as well as colorimetric methods do not, however, distinguish between pectins and alginates. Pectins can be degraded in solution with specific enzymes whereupon they become alcohol soluble. Alginates can then be determined in the alcohol-insoluble residue. Polyuronides can also be precipitated from preparations, mixtures, or foods with Ca^{2+} ions and thus separated from other polysaccharides. After hydrolysis to monomeric uronic acid residues [181], the latter can be analyzed by gas chromatography [29] or HPLC [196]. This method also allows analysis of the uronic acid composition of alginates and, after partial hydrolysis, the proportions of mannuronan and guluronan blocks. The proportions of M and G residues in an alginate preparation and their distribution in M, G, and MG blocks can also be determined by ^{1}H-NMR [182], [197] and circular dichroism [198]. As a result of their wide range of applications, no internationally recognized standard methods exist to assess the quality of alginates. Manufacturers therefore usually specify the viscosity or gel strength of their products by methods agreed upon with clients.

4.8. Applications

Food Industry. The applications of *alginates* in the food industry are based on

1. Their potential to form highly viscous solutions with outstanding suspension-stabilizing properties
2. Their stability at high temperature and high pH
3. Their reactivity with Ca^{2+} ions, which enables them to gel
4. The thermal stability of these gels [168], [171]

As a result alginates are used in almost all groups listed in Table 2. For acid products, *propylene glycol alginates* are used. In all of these applications, lump formation must be considered when adding the alginate to an aqueous system, similar to pectins. When sugar is part of the ingredients, some may be admixed with the alginate. When the application allows the addition of alginate as a solution, the alginate can best be solubilized by dosing it gradually in the vortex of a powerful mixer. For laboratory use the alginate can be moistened with alcohol. For all listed applications, only a few grams of alginate are added per kilogram of product; for the stabilization of foams a few milligrams per kilogram suffice.

Other Applications. Twice as much alginate is used in applications outside the food industry. Except for groups 17, 20, 23, and 26, all applications

in Table 2 have been described. Of greatest impact is group 31, which claims to cover ca. one-third of alginate sales. Groups 27 and 29 also represent a substantial market. One of the first applications of alginates was in the treatment of boiler water (group 32). The calcium is flocculated as calcium alginate and not deposited as scale. For this application, alginate paste is used, which does not have to be refined to the extent necessary for food applications. The strong swelling power of alginic acid makes it a good binding agent for tablets (group 24), and its calcium reactivity enables denture replicas to be made (group 25). The triethanolamine salt is often used as a thickening agent in cosmetic and pharmaceutical ointments. Another interesting application mentioned in the commercial literature is as a gel for embedding the roots of plants to protect them from mechanical damage and from dehydration after replanting. In the last decade alginates have been used in biotechnology research to immobilize bioactive cells and to purify enzymes [137].

4.9. Market

The alginate industry is limited to a small number of companies. Production plants are found in locations where suitable weed species are present (i.e., North America, Scotland, Brittany, and Japan). Alginate is also produced in the former Soviet Union. About 25 000 t of alginate is produced annually; ca. one-third of this is used in the food industry. The price of sodium alginate for food applications is ca. $ 9.0 – $ 15 per kilogram.

5. Carrageenan

Alphons C. J. Voragen and Svein Halvor Knutsen

Carrageenans belong to a family of polydisperse long chain galactans, which can be extracted from red seaweeds (Rhodophyta) [304], [305]. The major uses are as high quality ingredients in food and cosmetics with estimated worldwide sales approximately $ 263 × 10^6 in 1997 [306].

5.1. Structure

Carrageenans are build up by alternating 1,3-linked β-galactose (**G**-units) and 1,4-linked α-galactose (**D**-units) that can be partly esterified with sulfuric acid (**S**). In carrageenans with the ability to form a gel the major part of the 4-linked units are in the 3,6-anhydro form (**DA**). A short hand nomenclature system based on letters has been introduced [307] to simplify the old system based on Greek letters [308], [309].

Historically the three major commercial carrageenans types were named κ, ι, and λ with their corresponding structures and short names given in Table 5. Originally the two former (gelling family) were isolated based on their insolubility in KCl [310], whereas the latter formed the soluble fraction (nongelling family). These major types are representation in Figure 14. In the text the Greek nomenclature normally will be used for the three common commercial types only, whereas the letter system will be used to specify structural characteristics when appropriate.

Figure 14. The repeating structures of the most common commercial carrageenans and the relation to their 6-sulfated analogues

Table 5. Most common carrageenan structures in commercial samples

4-linked unit	3-linked unit	Greek letter name
DA	**G4S**	kappa (κ)
DA2S-G4S	**G4S**	iota (ι)
D2S,6S-G2S	**G2S**	lambda (λ)
DA	**G**	beta (β)

There are several biological factors that complicate the structural picture of carrageenans.

In general the **DA** (in κ-carrageenan) or the **DA2S** (in ι-carrageenan) might be replaced with their 6-sulfated precursor residues, **D6S** (μ-carrageenan) and **D2S,6S** (ν-carrageenan), respectively [311]. The conversion of precursors to 3,6-anhydrogalactose (**DA** or **DA2S**) occurs during biosynthesis in the algae [312], but can also be catalyzed by hot alkali during the commercial phycocolloid production. During the alkali treatment or the enzyme catalyzed elimination reaction the $^4C_1$ conformation of the 4-linked 6-sulfated precursor units (**D2S,6S** or **D6S**) is transformed into $^1C_4$ in 3,6-anhydrogalactose with the liberation of sulfate from position 6. The desulfatase enzyme has also been called “dekinkase” because it effects a change in the configuration of the transformed galactosyl unit and removes “kinks” present as equatorial-axial glycosidic linkages [204]. Some algae have a gametophyte generation producing carrageenans of the gelling family, and a sporophyte generation (both often identical in appearance), producing **D2S,6S-G2S** (λ) or structurally related carrageenans [313]. Such carrageenans have traditionally been ill defined due to difficulties in their characterization and are mostly obtained from *Chondrus* and *Gigartina* genera [306]. λ-Carrageenan can most probably only be transformed into a component containing a 3,6-anhydro bridge (**DA2S-G2S**, termed θ-carrageenan) during a hot alkaline treatment. Enzymes capable of catalyzing this reaction in the algae have not been detected and naturally occurring **DA2S-G2S** is rare [314].

In general the repeating sequence that dominates the structural character of a carrageenan is the basis for any nomenclature system. However, it should be stressed that the idealized structures most often are masked by precursors or other carrageenan elements. In fact by selecting the algal source carrageenans with wide **DA/DA2S** ratio can be obtained [315-317]. In addition to the carrageenan mentioned above in Table 5, which are the main constituents of commercial preparations, different carrageenan structures are constantly isolated from new sources [309], [314], [318] and/or found in small quantities in regular samples. Finally, algae containing molecules with a mixed carrageenan and agar (4-linked D-galactose replaced with 4-linked L-galactose) structure have been detected [319], [320], [321]. So far these extracts are not economically important.

In addition to sulfate, substitution by methyl ethers and pyruvate or other sugars, such as xylose, glucose, and uronic acid, may be present in a carrageenan sample. Nitrogen containing components such as proteins and pigments are common impurities (0.1–1 wt %). Since the viscosity of several commercial carrageenan solution can be reduced by the addition of protein degrading enzymes, some possible linkage to the carrageenan chain is suspected [322]. Carrageenans may therefore be considered as proteoglycans [304].

To complete the description of the carrageenan structure, the mean number of constituent sugars, their weight average molecular mass M_w, and the distribution of the molecules (polydispersity factor = $\langle M_w \rangle / \langle M_n \rangle$ must be given. Representative values are in the range of 300 000–600 000 and 2.3–5.1, respectively [305].

5.2. Sources and Raw Materials

Carrageenan has been used for several hundred years in Europe and the Far East, and the name is linked to the Irish village Carraghen, where Irish Moss (*Chondrus crispus*) was harvested and utilized in milk products [323]. During the last years the harvesting of natural Irish Moss populations has been reduced and is being discussed as an environmental issue in several countries. Natural resources are mostly harvested in temperate regions (Canada, Chile, and France) and at present the largest consumption is based on cultivated tropical seaweeds such as *Kappapycus alvarezii* [306]. For the major commercial products and sources see Table 6.

Table 6. Examples of carrageenans that are present in neutral* or alkali-treated extracts. n is restricted to the gametophytic generation and 2n is restricted to the sporophytic generation. The species considered as commercially most important are in bold phase.

Dominating structure (s)	Generic examples
DA-G4S	***Kappaphycus alvarezii***[a],*Hypnea musciformis*, ***Chondrus crispus***(*n*), *Chondrus ocellatus (n)*, *Gigartina tenella(n)*
DA2S-G4S	***Eucheuma denticulatum***[b], *Agardhiella tenera*, *Gymnogongrus concinna*,
DA2S-G4S and **DA-G4S**[c]	***Sarcothalia crispate***[d](*n*), ***Gigartina skottsbergii***[e](*n*)
DA-G4S ≈ **DA-G**	***Furcellaria lumbricalis***[f]
DA-G > **DA-G4S**	*Eucheuma gelatinae*
D2S,6S-G2S*[g]	***Chondrus crispus***[h](2*n*), ***Gigartina pistillata***[i](2*n*), *Sarcothalia crispate(2n)*, *Gigartina skottsbergii(2n)*
DA2S-G2S[j]	*Sarcothalia crispate(2n), Gigartina skottsbergii(2n)*
DA-G6S	*Phyllophora sp, Risoella verruculosa*

[a]Trade name (Eucheuma) cottonii or cottoni.
[b]Trade name (Euchuma) spinosum.
[c]Copolymers referred to as kappa-2 with weaker and less milk reactivity than **DA-G4S**. For a full discussion of several species see [317].
[d]Sandpaper [324].
[e]Pigskin [324].
[f]Danish agar, Furcellaran or κ-furcellaran.
[g]May contain other structures such as pyruvated residues (**GP,2S**).
[h]Cultivated in Canada.
[i]Obtained from Morocco.
[j]Occur only in alkali treated sporophytic extracts. For a more detailed explanation of nomenclature see [305], [307]. Information mostly extracted from [306] and [317].

5.3. Production

After harvesting the seaweeds material is washed to remove sand and stones and dried to a dry matter content of ca. 25 wt %. The carrageenan content can vary from 15–70 %, depending on the seaweed. The production of refined carrageenan is shown schematically in Figure 15. The dried algae are treated with alkali and ground to a paste. Alkaline conditions facilitate extraction of the macerated algae, retard acid-catalyzed depolymerization of the galactan and catalyze the conversion of C-6 sulfated precursor residues to 3,6-anhydrogalactopyranosyl residues, thus increasing the gelling potential of the product. The crude extracts are further purified by sieving and filtration by using a filter aid such as celite. If drum drying is anticipated, pigments are first removed with activated carbon. To prevent gelling, all of these operations must be carried out at higher temperatures.

Figure 15. Flow sheet for the production of carrageenans

Because as with pectin and alginates, dilute extracts must be processed to a dry product, the energy cost for dewatering and recovery of alcohol is an important factor. Isopropanol is used as the alcohol for precipitation of the carrageenan. An alternative process is available for κ-carrageenan by extruding the extract into a KCl solution, pressing the precipitate and removing water by freeze-thaw cycle. After drying and grinding several batches might be blended and/or standardized by the addition of salts and sugars. Furthermore, by selecting a milder alkaline extraction process than the conventional alkali modification, carrageenans with a remaining small fraction of precursor units and hence altered function might be obtained [324]. The most innovative processing procedures include enzymic tools based on molecular biology, mostly developed at the Goemar Laboratories, (Roscoff, France). Both stable enzyme preparations of glycosylhydrolases—to produce carrageenan oligosaccharides—as well as sulfohydrolases — to convert precursor residues into 3,6-anhydrogalactose on the polymer level have been cloned [325]. In the late 1990s [326] a semirefined carrageenan has been offered on the market. The product, Processed Euchuma Seaweed (PES), is regulated as E407b. Such carrageenan products are obtained by first treating the algae with hot KOH solutions, washing with water, and finally drying, bleaching, and grinding to a suitable particle size [327]. Under the conditions used the carrageenan is not extracted and the precursors, if present, are converted to 3,6-anhydrogalactose inside the algal material. PES will contain more acid insoluble matters and fiber components such as cellulose [328].

5.4. Analysis

Carrageenan preparations can be separated based on their solubility in aqueous KCl and further analyzed by several tools. The content of sulfate can be determined by gravimetry (FAO, 1992) and the content of 3,6-anhydrogalactose by the resorcinol reagent [329]. The content of both constituents can be determined by HPLC [330]. By a simple recording of the increase in the 3,6-anhydrogalactose content by the recorcinol reagent upon a hot alkaline treatment the level of precursors can be evaluated in a carrageenan sample.

The constituent sugars can be analyzed by *gas chromatography* after the introduction of a specialized hydrolysis and derivatization procedure to conserve the 3,6-anhydro units. This reductive hydrolysis in the presence of methylmorpholine-borane [363] can even be applied directly to seaweed samples for evaluation of carrageenan structure and taxonomy [331]. The use of partial reductive hydrolysis after methylation can discriminate between agaran and carrageenan backbone and its substitution [332]. *IR-spectroscopy* can be applied to study the position of sulfation but has some limitation for quantitative analysis. This technique can be applied directly to carrageenan [333] or to dried and milled material by the use of FTIR diffuse reflectance spectroscopy [334].

By far the most powerful technique for carrageenan analysis is *NMR spectroscopy* [335]. ^{13}*C-NMR* spectroscopy is preferred for identifying the different residues in a carrageenan sample since most of the signals (resonances) from the residues and even some signal splitting due to sequence effects are well separated [336]. However, a low signal to noise ratio is encountered and components below 5 % may not be detected. For ^{1}*H-NMR* the sensitivity is better but a distinction between the different components is more difficult since the different signals may overlap in a quite narrow region of the spectra. For routine applications ^{1}H-NMR can be applied to 1 mg samples and analyzed within 15 min [316], [337], [338]. Spectroscopy can also be used for the estimation of carrageenan in foods [339]. Combined with the selective degradation with carrageenase [311] and chromatography the major as well as the minor constituents may be identified [340]. Apart from data for sugar composition and sulfate substitution an important parameter for carrageenans is their molecular mass. At present the common method is HPLC based *size exclusion chromatography* (HPSEC), coupled to a Multi-Angle Laser-Light Scattering (MALLS) detector, absolute mass and the molecular mass distribution can be obtained [341], [342]. Typical tests to demonstrate the presence of carrageenan are the formation of a blue coagulate with methylene blue, positive sulfate reaction after acid hydrolysis, and the formation of much stronger gels by the addition of potassium chloride. Recent progress in the analysis of carrageenans in food is reviewed elsewhere [343].

5.5. Properties

Gelation. All forms of λ-carrageenan as well as the sodium salts of κ- and ι-carrageenan are soluble in cold water. The potassium and calcium salts of κ- and ι-carrageenans, however, dissolve only at 70 °C and form gels or—depending on the ionic strength—viscous systems upon cooling (Table 4). κ-Carrageenan is more sensitive to potassium ions, whereas ι-Carrageenan is more sensitive to calcium ions. Once a highly potassium sensitive carrageenan resembling κ-carrageenan was produced from *Furcellaria*, i.e., furcellaran or Danish agar [344]. This carrageenan has a mixed **DA-G4S** and **DA-G** structure. However, since this free floating algae became extinct from Danish waters the holdfast variety is at present collected in Canada and processed together with *Chondrus crispus*. From a solution of the three major types of carrageenans, κ- and ι-carrageenan can be precipitated by potassium chloride. To obtain a gel the carrageenan molecules must undergo a transition from a random coil structure into helices that aggregate upon cooling. In general the ion induced network formation [345] is an intermolecular association that requires a minimum degree of polymerization of about 100 [346]. It is still under debate whether the fundamental ordered state is a single or a double-stranded helix. Results obtained by high-performance size exclusion chromatography-low angle light scattering (HPSEC-LALLS) (see Section Analysis) originally suggested a doubling of the molecular mass for the ordered conformation [341], [347] and hence double helixes (Fig. 16). At present the common method is HPLC based Size Exclusion Chromatography, coupled to a Low- or a Multi-Angle Laser-Light Scattering (LALLS or MALLS, respectively) detector.

Figure 16. Gelation of carrageenans by formation of double helices and aggregation of helices [348]

However, the findings based on light scattering data have been questioned due to the preparation method of the solution and the concentrations used, and result have been presented in favor of single helixes of ι-carrageenan [349]. The carrageenan gels are thermoreversible and upon heating, the helices unfold, the molecules go in solution again as random coils and the gel melts. In the gel state the aggregation of helices may continue, the network contracts, and the gel becomes brittle (short) and shows syneresis. The inability of λ-*carrageenan* to form gels can be explained by the occurrence of **D2S,6S** units in its backbone. A solubilized preparation rich in κ- *carrageenan* gives a firm gel with a setting point of 40 °C and a melting point of 55 °C at a concentration of 0.5 %, in the presence of 0.2 % potassium salt. The gel strength increases strongly with increasing concentration of potassium ions; however, potassium ion concentrations > 0.2 % are unacceptable because of taste. Also, addition of sugar increases the gel strength. Both additions also increase the setting temperature, as well as the melting temperature, of the gels. The hysteresis, i.e. the difference between melting and setting temperature, remains small and is ca. 15 °C. The gels are brittle and have a tendency to become opaque and show syneresis. This can be prevented by adding ι-carrageenan. Gels of ι-*carrageenan* alone are transparent, they show no syneresis and little hysteresis. Due to the presence of **DA2S** residues, which may act as a wedging group and prevent tight aggregation of double helices, the gels are rather weak. Furthermore, the observation that gelation of a commercial ι-carrageenan (**DA2S**-units) showed a small specificity towards monovalent cations was interpreted as being due to the inclusion of a small proportion of κ-carrageenan (**DA**-units) [350].

Viscosity. In a solution with low ionic strength the carrageenan chains are extended due to the electrostatic repulsion of the negatively charged sulfate groups and the resulting solutions are highly viscous. The viscosity increases with concentration and decreases by addition of salts due to charge shielding, and will decrease exponential upon heating. Viscosity will be reasonable reversible upon cooling as long as the condition for maximum stability of the molecular mass is kept (pH 9). The viscosity of soluble carrageenan forms can be measured in 1 % solutions at room temperature, but because of gelation at intermediate temperature, viscosity is normally measured in 1.5 % solution at 75 °C. At this temperature values up to 800 mPa·s have been measured for a 1.5 % solution. In industrial applications measurements are performed with rotational viscometers. Since carrageenan solutions have pseudoplastic behavior the shear rate must also be reported. The molecular mass (M_w) dependence of the intrinsic viscosity [η] is given by the Mark-Houwink equation:

$$[\eta] = K(M_w)^a$$

The constants *K* and *a* are dependent of the carrageenan type and the solvent. A value for *a* close to unity indicates rigid rod-like structure [351].

Synergistic Effect with Other Gums. Of particular interest is the interaction of κ-carrageenan with locust bean gum galactomannan. By partially replacing the κ-carrageenan with locust bean gum, which does not gel on its own, a stronger gel with improved properties is obtained. It becomes more elastic, and has a lower tendency to syneresis and to become opaque. Similar observations were made with konjac glucomannans. The smooth regions of the mannan chain (i.e., regions with no galactose or glucose side groups) are thought to bind to the double helices of the κ-carrageenan, forming mixed junction zones [207], (Fig. 17). These mixed junction zones have a lower tendency to form tightly packed aggregates. The industry has placed preparations on the market that exhibit constant gel strength and gel characteristics by blending different lots and adding potassium salts, sugar, and possibly locust bean gum. Because carrageenans may form lumps when added to water, premixing with sugar or adding the carrageenan in a powerful mixer is recommended. Carrageenans are also useful in altering the textural properties of a starch system. Adding *i*-carrageenan (0.5 %) to a starch system increases the viscosity as much as 10 times, whereas no effect is obtained from *k*-carrageenan [352].

Figure 17. Synergistic gelation between helix-forming carrageenans and agar with galactomannans by direct association of smooth regions of the mannan chain with double helices in the seaweed polysaccharides [209]

Stability. Carrageenans are not stable under acidic conditions, because the 3,6-anhydro ring and the 1 ⟶3 linkages are easily hydrolyzed. The substitution with 2-sulfate (**DA2S**) introduces some stability. Carrageenan solutions can be sterilized at pH > 4.5 but some reduction in molecular mass will occur [353]. In general decrease in molecular mass might be encountered during dialysis and due to autohydrolysis during freeze-drying or long storage. Gelled carrageenans are more stable and the common microorganisms found outside the marine environment do in general not degrade carrageenans.

Reactivity with Proteins. Carrageenans possess a strong anionic character because of their sulfate groups. These charges as well as associated

ions (Na^+ versus K^+ and Ca^{2+}) and the conformation of the sugars in the chain determine the properties of carrageenans. Reactivity with proteins can be observed both with carrageenan of the gelling and nongelling family, but some chain regularity is important in different types of interactions [351]:

1. Below the pH of the isoelectric point (I-pH) of the protein the positively charged protein and the negatively carrageenan form a complex, which might result in a precipitate depending on the net charge ratio.
2. Above I-pH, when both polymers are negatively charged, the interactions are mediated by polyvalent cations such as Ca^{2+}.
3. Finally, interaction with a positively charged part of a molecule with a net negative charge may occur.

In milk systems a highly specific interaction between κ-casein and carrageenans has been established that causes κ-casein particles or casein micelles to attach to the carrageenan chain. When the molecular mass of the carrageenans is sufficient, helical regions can form and aggregate and a gel network is obtained. This can occur only with the gel forming κ- and ι-types. Addition of 0.2 % κ-carrageenan to milk at the pasteurization temperature and cooling to 43 °C, gives a firm gel that melts again at 60 °C.

Weak networks form at carrageenan concentrations as low as 0.02 %, which can fix casein particles. In chocolate milk, for instance, this network holds the cocoa suspension and, in creams the lipid globules. It is suggested that both type (2) and (3) are important in the gelation of milk and to stabilize chocolate milk. The ability to stabilize casein micelles is in the order **DA-G4S**>**DA2S-G2S**>**D2S,6S-G2S** [351]. The reaction between milk proteins and carrageenan may synergistically increase the gel strength about 10 times, and carrageenans forms milk gels such as flans at a concentration of 0.2 %. ι-Carrageenan forms elastic, κ forms brittle, and λ-carrageenan forms weak milk gels.

5.6. Applications

Medical Applications. Carrageenans are widely used in clinical tests for anti-inflammatory agents by their ability to induce so-called rat-paw edema. Furthermore, it has been shown that carrageenan may act as anticoagulant (heparin analogue) and by activating the Hagemann factor [354]. Carrageenans may also act as immunosuppressor agents [355] and show toxicity against macrophages [356]. It should be noted that some of the earliest studies may have been performed with quite ill defined carrageenans. Carrageenans have more recently been considered as potential antiviral agents [357], [358]. It has been shown that the activity is related to the sulfate substitution pattern and that **D2S,6S**-residues as found in precursor- and λ-carrageenan have the highest reactivity [359].

Other Applications. Carrageenan oligosaccharides have been investigated as fertilizers, stimulants of growth and reproduction and to stimulate defense mechanisms in plants [360].

Discussions on carrageenans for use as paint stabilizer, beverage clarifier, controlled release agent of drugs, in viscosifier in food and tooth paste and in a waste different other applications in the food, nonfood, and medicine sector are found elsewhere [328], [351], [361].

5.7. Physiological Properties

Carrageenan has been given GRAS status by the FDA, based on the assumptions that high molecular mass carrageenans are not absorbed in the intestine, and food grade carrageenans are not ulcerogenic in humans. However, it has been shown that commercial carrageenan samples have a quite wide molecular mass distribution and that carrageenan may be degraded under stomach juice simulated conditions [362]. Therefore the matter is constantly under debate.

[Top of Page]

6. Agar

Alphons C. J. Voragen, Abdelwahab Riad, Rachid Lebbar

Agar, also called agar-agar, kanten, or gelose, is the oldest known gel-forming polysaccharide.

Discovered in the 17th century in Japan and consumed for 200 years, agar is extracted from certain marine red algae of the class Rhodophyceae mainly from *Gelidium* and *Gracilaria* species, growing essentially along the coasts of Morocco, Spain, Portugal, Chile, Japan, and Korea [210].

The extreme inertness of agar led KOCH and PETRI in 1882 to use it as a medium in which to grow bacteria [211]. In his now classical preliminary note on the tubercle bacillus, published in 1882, KOCH formally announced agar as a new solid culture medium. Up to date, no better solidifying agent in microbiological media has been found. At present, agar has become an indispensable substance in microbiological, biotechnological, and public health laboratories, and an important colloid in other industries. Agar is also a permitted gelling, stabilizing, and thickening agent for food applications, authorized in all countries without limitations of daily intake [210]. It finds use in many food industries such as confectionery, bakery, pastry, beverage, sauces, wines, spreads, spices and condiments, meats and fishes, dairy, jams, etc.

Apart from its ability to gelify aqueous solutions and produce gel without the support of other agents, agar can also be used as a safe source of dietary fiber since it is not digestible by the human body.

Agar is insoluble in cold water, hardly soluble in hot water, and readily soluble in boiling water. In food or technical preparations of a high total solids content, agar should be solubilized separately before adding the other ingredients of the formulation. Usual agar is therefore not compatible with the continuous industrial processes.

Quick soluble agar (QSA) is a new agar version developed in 1993 by Setexam. It is obtained from a selected red seaweed and according to a patented manufacturing process without any chemical or genetic modifications.

Unlike traditional agar QSA has a great ability to dissolve in water or in milk at temperatures > 65 °C or during the pasteurization stage, without need to be cooked or heated to boiling, and is therefore compatible with most of the continuous industrial processes.

6.1. Production

Agar is insoluble in cold water but is colloidally dispersible in boiling water. Hence, most commercial agars are produced by hot water extraction. Other methods are possible, such as an extraction with glycerol, anhydrous ammonia, or other solvents [212], but the traditional process employing hot water is the most recommended for the agar destined to food applications.

The agar extraction procedures vary according to the treated seaweed variety. They generally follow three stages (see Fig. 18):

Extraction
Purification
Dehydration

Figure 18. Flow sheet of traditional agar extraction

First, the seaweeds are carefully washed with water in order to eliminate marine salt and foreign matter such as sand. The extraction is made by hot water under pressure or in open tank if the seaweeds have undergone an alkaline treatment. This latter is mainly applied to *Gracilaria* seaweed in order to lower the sulfate content in the resultant agar.

The extraction juice, composed of 99 % water and 1 % agar, is filtered at hot temperature, then cooled at room temperature. The resulting gel is dehydrated under mechanical pressure or by freezing-thawing.

In *pressure dehydration* a pressure of 49 – 98 N/cm^2 is applied to press the gel through intercalated filters. Water passes the filters and the agar molecules are retained as filter cake.

Gel freezing is carried out at – 18 °C. At that temperature the agar molecules are excluded selectively from the ice network and form strips. The thawing step melts the ice and agar strips are recovered selectively.

These two operations of dehydration taken individually remove about 70 % of the initial water content. A part of the residual moisture is then eliminated by drying with hot air. The dry agar flakes are ground to prepare a final product in powder form with different mesh sizes.

6.2. Structure and Gelling Mechanism

Structure. The elucidation of the complex chemical structure of agar by ARAKI had revealed the presence of two dominating polysaccharides: a virtually neutral polymer termed agarose, and a charged polymer termed agaropectin [213]. ARAKI deduced the structure of *agarose* to be 1,4-linked 3,6-anhydro- α-L-galactose alternating with 1,3-linked β-D-galactose [214-216].

Agaropectin is thought to have the same repeating unit as agarose, although some of the 3,6-anhydro-L-galactose residues can be replaced with L-galactose sulfate residues [217], [218] and the D-galactose residues are partially replaced with the pyruvic acid acetal 4,6-*O*-(1-carboxyethylidene)-D-galactose [217], [219]. Fractionation studies on DEAE Sephadex A-50 carried out by DUCKWORTH and YAPHE [217], [220] have indicated that agar is not made of one neutral and one charged polysaccharide but is composed of a complex series of related polysaccharides which range from a virtually neutral molecule to a highly charged galactan. These studies indicated that in agars containing 4,6-*O*-(1-carboxyethylidene)-D-galactose, this charged residue is always found in regions of the molecule with low sulfate content. Agars in which the D-galactose residues are partially replaced with 6-*O*-methyl-D-galactose contain this 6-*O*-methylated monosaccharide evenly distributed throughout the neutral and charged regions of the complex [217], [218].

Studies by GUISELEY in 1970 [221] indicated that in naturally occurring agars, an increase in gelling temperature occurred with increasing methoxyl group content. In this way, the gelling temperature of an agar from a *Gracilaria* species with high methoxyl content is higher than that of an agar from a *Gelidium* species with little or no methoxyl content.

Gelling Mechanism. The gelling properties of an agar are essentially effected by the agarose part [222], [223]. The rheological properties of the gel are strongly influenced by agaropectin.

Agar forms high strength gels which are completely reversible with a hysteresis cycle over a range of 40 °C (see Fig. 19): Upon dissolution in boiling water agar acquires a random coil configuration. The subsequent gel formation proceeds in two steps. The decrease in temperature of the hot solution, slightly above the gelification temperature, provokes at first the formation of a double-helical conformation of the agarose chains [224-226]. The second stage is the self-associations by nucleation of these double helices to form aggregates [227], [228]. The obtained agar gel is completely heat-reversible since it remelts at above 85 °C (see Fig. 20).

Figure 19. Hysteresis of 1.5 % agar gels

Figure 20. Gel formation mechanism in aqueous agar solutions

The gelation process of agar is not linked with the cations present such as in the case of alginates, some pectins, or the carrageenans, but is only due to formation of hydrogen bonds which explains the thermoreversibility of agar gels. Three equatorial hydrogen atoms of the 3,6-anhydro- α-L-galactose residue are believed responsible for constraining the molecule so as to form a helix with a threefold screw axis [229]. Interaction of these helices causes gel formation.

Replacement of 3,6-anhydro- α-L-galactose residues with L-galactose sulfate causes kinks in the helix, and hence a polysaccharide of lower gel strength is formed [230].

6.3. Quick Soluble Agar

Production. If the gelling mechanism is superposed to the extraction procedure, it can be concluded that agar powder is a dehydrated gel and the

molecules adapt the aggregated double helix conformation. That is why a certain amount of heat energy is required to dissociate the hydrogen bonds and to dissolve the agar molecules in random coil form.

The amount of heat energy required can be considerably lowered if the molecules in agar powder are not obtained in aggregated double helix but in random coil configuration. Setexam managed to finalize a new procedure including neither a chemical transformation nor a genetic modification for the production of Quick Soluble Agar (see Fig. 21).

Figure 21. Comparison of production processes of traditional agar and QSA

Properties. QSA has the same physical and chemical characteristics as traditional agar, i.e., gel strength, pH, color, total ash, etc., except for solubility. Contrary to traditional agar that dissolves only in boiling water, QSA dissolves instantly in water or milk at 65 °C or during pasteurization. This property of QSA simplifies the manufacturing of food or technical products, in batch and continuous processes. It eliminates all the disadvantages met with the traditional agar utilization such as the necessity of a separated dissolution stage, a large initial volume of water, blackening on cooking inner sides, degradation of the gelling power, etc.

Application of QSA is very easy, as it is introduced during the preliminary stages of any food or technical preparation and dissolves instantaneously during the heating, the pasteurization or the sterilization stage, which makes it compatible with most of the continuous industrial processes.

The thermoreversibility of QSA gels facilitates its handling and recycling; and its unmatched natural hysteresis offers a definite advantage particularly with regards to the shelf life of food or technical preparations.

The QSA reacts selectively with the water portion of any recipe in a wide range of pH values without interaction with neither the present cations nor with the present organic matters.

7. Gum Arabic

Alphons C. J. Voragen

Gum arabic is a dried exudation obtained from the stem and branches of acacia trees, *Acacia senegal* L. or *Acaica seyal* (fam. Leguminosae). For commercial production the trees are tapped or drilled. After drying in air, the exudate tears are harvested by hand and transported to central collecting stations where they are sorted according to size, color, and contamination with impurities. Harvesting takes place during October to June. A young tree yields ca. 0.9 kg and an older tree up to 12 kg of gum annually. The trees grow in the tropical and subtropical areas of Africa. Exproting countries are Sudan, Tschad, Nigeria, Mali, Mauretania, Senegal, and Ethiopia. Acacia species can be found worldwide, but only the exudates of *A. senegal* and *A. seyal* may be traded as gum arabic. World production is around 40 000 t/a.

Raw gum is still sold in substantial quantities; however, a precleaning by air classification to remove sand, fines, and bark is required. The product can be further processed to a kibbled, granular, or powdered form. Importers in Western Europe and the United States produce speciality products for particular applications. For this purpose the gum is dissolved, and the gum solution is exposed to sieving or centrifugation and then drum or spray dried [1-4], [231].

Structure. Gum arabic consists of three principal fractions, an arabinogalactan fraction (AG) with very little protein, representing 88 % of the gum und having a molecular mass of 250 000; a high molecular mass (1.5×10^6) arabinogalactan – protein complex (AGP) representing about 10 % of the gum; and a glycoprotein (GI) with a molecular mass of 200 000, making up 1.2 % of the gum. By treatment with proteolytic enzymes the AGP fraction is degraded to fragments with a molar mass similar to AG. The wattle blossom model has been proposed to describe the structure of AGP: Carbohydrate blocks with molecular mass of ca. 250 000 are linked together by a main polypeptide chain. The carbohydrate blocks consist of a β-1,3-linked galactopyranose backbone chain, with numerous side chains linked through β-1,6-galactopyranose residues and containing arabinofuranose, arabinopyranose (Ara), rhamnopyranose (Rha), glucuronic acid (GlcA), and 4-*O*-methylglucuronic acid. The sugar moieties occur in the ratio Gal 36, Ara 31, Rha 13, and GlcA 18. The structure of a representative segment is shown in Figure 22 [232-235]; depending on growth conditions and age, some structural variations exist.

Figure 22. Structural features of gum arabic

Properties. The molecular mass of gum arabic averages around 500 000; the glucuronic acid content (including 4-*O*-methylglucuronic acid) of ca. 18 % makes gum arabic an acidic polysaccharide. With a cation exchanger or by washing with acidified alcohol, gum arabic can be converted to arabinic acid, which exhibits the titration curve of a strong acid. A 5 % solution has an apparent dissociation constant of 10^{-3}. Solutions in water have a pH of 2.2 – 2.7.

The most striking feature of gum arabic is its *extreme solubility in water*. Due to its highly branched, compact structure, solutions containing up to 40 % gum arabic can be obtained, which still exhibit typical Newtonian flow behavior. Compared to other polysaccharides of similar molar mass, the viscosity of these solutions is very low (Table 4). Viscous solutions are obtained only at concentrations > 30 %, where effective molecular overlap begins to occur and solutions gradually assume pseudoplastic behavior. The *viscosity* of gum arabic solutions is highest in the pH range 4.5 – 5.5; in this range the carboxyl groups are ionized to a large degree. Addition of salts strongly decreases the viscosity due to suppression of the electrostatic charge. Gum arabic is compatible with most other hydrocolloids except for alginates and gelatin. It is also surface active and has been widely used to *stabilize oil-in-water emulsions*. The AGP fraction is responsible for its emulsifying ability. The polypeptide chain is believed to be at the periphery of the molecule and to adsorb onto hydrophobic surfaces. Gum arabic has been shown to be heat sensitive; proteinaceous material (AGP and GI) precipitates on prolonged heating, and as a consequence the solution viscosity drops considerably and the emulsifying ability is lost [231], [232], [235], [236].

Gum arabic can be *precipitated* with trivalent cations and by salts such as silicates, borates, and mercury nitrate. It is insoluble in oils and most organic solvents but soluble in aqueous ethanol up to ca. 60 % ethanol. In gum arabic preparations enzyme activities have often been

demonstrated, for example, oxidases, peroxidases, amylases, and pectinases. For applications in foods, these activities are undesirable, and the enzymes must be inactivated by heat [2].

Applications, Market. Gum arabic was a commodity 4000 years ago in Egypt, and was used for the manufacture of cosmetics, dyes, and tinctures. Half of the amount imported by the United States is used in the food industry; this makes gum arabic one of the most useful plant hydrocolloids. The annual production has risen to > 50 000 t/a [231], [234]. Gum arabic is used in groups 2, 4, 8, and 11 (Table 2). Dried, powdered flavors (group 5) constitute a major application. High gum concentrations allow spray drying without loss of flavor. Its emulsifying and stabilizing ability, in combination with its use in high concentrations, makes gum arabic attractive for pharmaceutical and cosmetic applications (groups 16 and 21). In industrial applications such as an adhesive on gummed envelopes and stamps (group 20), and as a dispersive agent in dyes and tinctures, gum arabic is being replaced by starch and cellulose derivatives. Prices vary between $ 3 and $ 8.5 per kilogram.

[Top of Page]

8. Gum Tragacanth

Alphons C. J. Voragen

Gum tragacanth is the exudate from breaks or wounds inflicted in the bark of shrubs of the *Astragalus* species, particularly *Astragalus gummifer* Labillardière (Leguminosae family), which are found in the mountainous regions of Iran, Syria, and Turkey. The gum was described by THEOPHRASTUS in the third century B.C. The name tragacanth is of Greek origin and means goat horn. It probably refers to the curved shape of the 2 – 3-mm-thick ribbons that represent the better quality gum. Gum tragacanth also exists as flakes, which are of poorer quality. The bushes are carved to stimulate gum production. Ribbons are obtained from April to September; flakes are formed in the following months until November. The translucent, whitish, elastic ribbons, which originate predominantly in Iran, are considered the best quality. The harvest is collected at central stations and is exported mainly to the United States and the United Kingdom. Importers process the raw materials to standardized powders [1-4], [232], [233], [237]. Prices range from $ 16 – $ 21 per kilogram; the annual harvest is ca. 3000 t/a.

Structure. Gum tragacanth is composed of tragacanthic acid, which is the major component, and a nearly neutral *arabinogalactan* that is water insoluble but swells to a gel. The constituent sugar residues of this arabinogalactan are: 75 % L-arabinose, 12 % D-galactose, 3 % D-galacturonic acid methyl ester, and L-rhamnose. *Tragacanthic acid* is water soluble and consists of a backbone of 1,4-linked α-D-galactopyranosyluronic acid residues (polygalacturonic acid chain as in pectins) with short side chains including single-unit β-1,3-linked D-xylopyranose, dimeric β-1,3-linked D-xylopyropyranosyl-1,2- α-L-fucopyranose, and dimeric β-1,3-linked D-xylopyranose-1,2-D-galactopyranose. The structure is shown schematically in Figure 23. The sugar moieties are present in the relative proportions D-galacturonic acid 43 %, D-xylose 40 %, L-fucose 10 %, and D-galactose 4 %. Tragacanthic acid has a high molecular mass (840 000) and gives accordingly highly viscous solutions (Table 4) that exhibit pseudoplastic behavior at concentrations > 0.5 %. A 1 wt % solution can have a viscosity of 3600 mPa · s. Accompanying Ca^{2+} and Mg^{2+} ions may contribute to the high viscosity and gelling properties of gum tragacanth solutions. The viscosity changes little in the pH range 2 – 10 and is stable during heating in a 1 % acetic acid solution [1-4], [232], [233], [237].

Figure 23. Structural features of gum tragacanth

Applications, Market. The application of gum tragacanth in foods and acid products is based on its heat stability, and its stabilizing ability in emulsions and suspensions. Therefore, gum tragacanth is of particular interest for group 12 (Table 2). Because of the slimy consistency of gum tragacanth dispersions, this gum can also function as a fat replacer. Other applications are mentioned in groups 8 and 9. Outside the food industry gum tragacanth is also used in groups 16, 18, and 21. A special application is its use in spermicidal jelly.

[Top of Page]

9. Gum Karaya

Alphons C. J. Voragen

Gum karaya is also named Sterculia gum, Kadaya gum, or Indian gum; it is the dried exudate from the bark of *Sterculia urens* or other *Sterculia* species (Sterculaceae family), trees occurring throughout northern and central India. The formation of exudate is artificially initiated by carving the bark. After a few days the exudate can be harvested as large irregularly shaped tears, which may weigh 1 kg or more. From April to June, 4.5 kg can be obtained per tree. The gum is sold to merchants at central trade stations and precleaned by removing pieces of bark; the tears are broken and graded according to purity and color. In consumer countries, the gum is then milled to a homogeneous powder. In the past, gum karaya was sold in a blend with gum tragacanth; in the meantime, however, it has found many applications because of its specific characteristics. The annual production is estimated at 5000 t, the larger part of which is used in the United States. Prices are ca. $ 4.8 –$ 6.4 per kilogram. Expansion of the production requires afforestation and takes at least 10 years [1-4], [232]. Gum karaya is a highly acetylated, acidic polysaccharide with a backbone chain of alternating 1,4-linked α-D-galacturonopyranosyluronic acid residues and 1,2-linked α-L-rhamnopyranosyl residues. Singleunit β-D-galactopyranosyl- and β-D-glucuronopyranosyluronic acid side chains are attached to O-2 and O-3 of the galacturonic acid residues, whereas half of the rhamnose residues have 1,4-linked β-D-galactopyranosyl residues at O-4 (Fig. 24). The molecule also has 13 wt % acetyl groups. Gum karaya is poorly water soluble; however, it swells readily in cold water to many times its original volume, particularly when finely ground (<200 mesh), giving a dispersion that appears homogeneous. By using an autoclave, solutions of up to 20 % can be obtained; their viscosity is, however, decreased as a result of degradation. Gum karaya solutions deviate from Newtonian behavior and exhibit viscoelasticity. Under alkaline conditions, deacetylation occurs and converts a gum karaya suspension into a ropy mucilage [232], [233]. The ability to swell and its resistance to enzymic and microbial degradation make powders of gum karaya good adhesives for dentures. Particles of ca. 0.6 mm swell to 60 – 100 times their volume and form a mucilage that allows drainage. Food applications are in groups 9, 11, 12, and 13 (Table 2). Gum karaya has also found use in the paper industry (group 29) and textile painting (group 30).

Figure 24. Structural features of gum karaya

[Top of Page]

10. Gum Ghatti

Alphons C. J. Voragen

Gum ghatti, also called India gum, is an exudate of *Anogeissus latifolia* (Combretaceae family), trees that grow in the deciduous forests of India and Sri Lanka. The Indian word gath means mountain pass and refers to the trade routes for this gum. The exudate usually has the shape of 1- cm-thick

beads or tears, which may be colored by absorption of tannins from the bark. Also, dust and other particles may stick to the gum. Gum ghatti is harvested mainly in April and graded by traders according to color and impurities. The highest quality is pure and only lightly colored. Importers, particularly in the United States, purify and standardize the gum by grinding, sieving, and blending or by solubilization in water, filtration, and spray drying. It is of minor importance, with an annual production of ca. 1000 t [4].

Gum ghatti is composed of D-galactose, D-mannose, D-glucuronic acid, and L-rhamnose. A complex array of single-unit and oligomeric side is attached to a chain of alternating 1,4- β-D-glucuronic acid and 1,2- α-D-mannopyranose residues. The side chains comprise several 1,6-linked D-galactopyranose units, some terminated by glucuronic acid, joined to the mannopyranose residues at O-3 through 1,3-linked L-arabinopyranose residues. Single-unit L-arabinofuranose residues can also be found, some attached to the O-6 of mannopyranose residues, and other short sequences of L-arabinofuranose [233], [238]. *O*-acetyl groups have also been found. A schematic presentation of the structure is shown in Figure 25. In its acid form, gum ghatti has an equivalent mass of 1067; the gum occurs as the calcium or magnesium salt. The gum is not entirely soluble in cold water, but 90 % can be solubilized by maceration and heating at 90 °C. Removal of the divalent cations enhances solubility. The remaining 10 %, which is chemically identical to the soluble portion, is strongly swollen and also contributes to the viscosity [192]. Spray-dried preparations are completely soluble in water; they give, however, a lower viscosity of the aqueous solutions. The viscosity of gum ghatti solutions is higher than that of gum arabic solutions; viscosity increases quadratically with concentration. Like gum arabic, gum ghatti is an excellent stabilizer of emulsions and suspensions, and has found application in wax suspensions and pastes, oil emulsions, polishes, syrups, and as a dispersive agent in dried, vitamin-rich oil suspensions.

Figure 25. Structural features of gum ghatti

[Top of Page]

11. Xanthan Gum

Alphons C. J. Voragen and Ian Challen

Xanthan gum is the extracellular, high molecular mass heteropolysaccharide produced by the aerobic fermentation of *Xanthomonas campestris* NRRL-B1459 [1-5], [239]. The production of xanthan gum goes back to the investigations of JEANES and coworkers in the early 1960s at the Northern Regional Research Laboratory of the United States Department of Agriculture, Peoria, Illinois, in the framework of a large screening program for slime-producing microorganisms of industrial interest [240].

11.1. Production

Commercial production is carried out by a batchwise, submersed fermentation under strong aeration. During fermentation the bacterial cells are kept under a constant stress to direct their metabolism to metabolite production instead of growth. This is achieved by proper selection of medium composition. The medium cost forms a significant part (ca. 25 %) of the total production cost; the sugar concentration is adjusted so that it falls as low as possible at the end of the fermentation cycle, but depletion must be avoided to prevent the microorganisms from using the polysaccharide as a substrate [241]. For xanthan gum production, a typical medium contains a nitrogen source, phosphate and magnesium ions, trace elements, and glucose, which is kept at < 5 %. The pH must not be below 7. After 96 h at 30 °C, less than 0.1 % glucose is left in the medium, and a conversion to polysaccharide of more than 50 % can be obtained.

In the patent literature [242], much attention is devoted to propagation of the starter culture. In this stage, nitrogen is supplied by organic sources (e.g., soy peptone or corn steep liquor), which also contain some growth factors. During the main fermentation, nitrogen is supplied by mineral salts (e.g., ammonium nitrate). A typical composition of the medium at this stage is 0.06 % ammonium nitrate, 0.5 % potassium dihydrogenphosphate, 0.01 % magnesium sulfate heptahydrate, 2.25 % glucose, and 97.18 % water (Fig. 26). After inocculation of 5300 L of medium with 227 L of starter culture and vigorous aeration for 72 h at 28 – 31 °C, 77 kg of hydrocolloid can be recovered. The remaining medium contains < 0.1 % glucose. This means a conversion of 64.7 % and a final concentration of the polysaccharide of 1.45 %, which gives the medium a viscosity of 3000 mPa · s at 25 °C (Brookfield Viscometer, 60 rpm).

Figure 26. Flow sheet for the manufacture of xanthan gum

The usual precautions must be taken to preclude contamination of the batch fermentation through the culture medium, equipment and accessories, air, and neutralizer; thus it is doubtful if the batch operation can be replaced by a continuous process. Also the stability of the bacterial strain is a point of consideration. Since *Xanthomonas* bacteria do not form spores, the fermentation can be stopped by heat treatment in a heat exchanger. Further downstream processing involves centrifugation, filtration, and precipitation with ethanol or isopropanol as used for other hydrocolloids. The high viscosity of the fermentation liquor must be reduced by dilution with water or alcohol. The precipitate, dried by vacuum or with hot air, is processed to a marketable article by grinding and sieving. The powder is off-white to yellow in color.

11.2. Structure and Properties

Chemical Structure. Xanthan is a heteropolysaccharide composed of D-glucose, D-mannose, and D-glucuronic acid. It has a β-1,4-D-glucan (cellulosic) backbone substituted through C-3 on alternate glucose residues with a trisaccharide side chain consisting of β-D-mannose-(1,4)- β-D-glucuronic acid-(1,2)- α-D-mannose. The terminal mannose moiety may have pyruvate residues linked to the 4- and 6-positions, the internal mannose unit is acetylated at C-6 (Fig. 27) [243]. X-ray diffraction studies on oriented xanthan gum fibers [244] identified the molecular conformation as a right-handed five-fold helix with a pitch of 4.7 nm. In this conformation the trisaccharide side chain is aligned with the backbone and stabilizes the overall conformation by hydrogen bonding [245].

By modifying the biosynthetic pathway for xanthan production, the carbohydrate structure and the substitution pattern of the polymer can be genetically controlled. In this way, polysaccharides with quite different properties can be obtained [246].

Xanthan gum has a *molecular mass* of ca. 2×10^6. Since the structure and the molecular mass are genetically controlled, hydrocolloids with similar molecular mass and similar properties are obtained.

Figure 27. Structural features of xanthan gum

Solution Properties. Xanthan gum is completely soluble in hot or cold water. The gum can be hydrated in sugar solutions up to 60 %. The viscosity of the gum solution is a function of its concentration in the dispersion [247]. *Aqueous solutions* of xanthan gum are extremely viscous (Table 4) and pseudoplastic (i.e., they exhibit a reversible, highly shear-thinning behavior) [248] resulting from the conformation (rod-like) structure and the high molecular mass of the polymer [249]. A 0.25 % solution in water containing 1000 µg/g NaCl and 147 µg/g $CaCl_2 \cdot H_2O$ has a viscosity of ca. 1000 mPa · s at a shear rate of 1 s^{-1} which decreases to ca. 50 mPa · s at a shear rate of 100 s^{-1}. The property of shear thinning is made use of in food processing and in improving the sensory qualities of food [250]. Equations relating apparent viscosity, concentration, shear rate, and temperature have been reported [251].

Xanthan gum solutions exhibit higher viscosities than other gums at the same low concentration. Shear thinning is more pronounced due to the semi-rigid conformation (compared to the random coil conformation of the other gums). The formation of a weak gel network results in high yield point values. Theses interactions are shear-reversible. 1 % Xanthan gum in a 1 % KCl solution has a yield value of ca. 11 300 mPa compared to 4000 mPa for guar gum, 830 mPa for hydroxypropyl methyl cellulose (HPMC) and 360 mPa for locust bean gum (LBG). At a concentration of 0.3 % xanthan gum exhibits a yield value of 500 mPa while the other gums mentioned have no significant yield value. This quality is responsible for xanthan gum's ability to stabilize emulsions and dispersions [252].

Effect of Salts. In the presence of salts the solution viscosity is stabilized and maintained; polyvalent cations, however, can precipitate xanthan gum under alkaline conditions. Xanthan gum solutions are compatible with high concentrations of various salts [253].

Effect of Temperature. At low ionic strength xanthan gum solutions undergo a thermal transition (i.e., melting), as can be detected by a viscosity change [254]. Optical rotatory and circular dichroic transitions are coincident with the viscosity change, indicating a conformation transition. These data are consistent with the unwinding of an ordered structure into a random coil [255]. The transition temperature can be increased to > 90 °C when small amounts of salt are added [257].

The viscosity of a xanthan gum solution containing salt is almost unaffected over the temperature range 10 – 90 °C. Sterilized food products containing xanthan gum loose only ca. 10 % of their viscosity — much less than products stabilized with other hydrocolloids such as guar gum, alginate, and carboxymethyl cellulose (CMC).

In foods intended for use in microwave ovens xanthan gum eliminates moisture separation. At a gum level of 0.4 % the viscosity is not affected by electrolytes while at a 1 % gum level the viscosity increases significantly.

Effect of pH. The secondary structure (the side chains wrapped around the backbone) imparts xanthan gum stability against degradation by acids, bases, heat treatment, freeze – thaw cycles, enzymes and extended mixing processes [239].

Xanthan gum solutions are stable over a wide pH range (ca. < 2.5 to > 11) [247]. At pH $\simeq$ 9 and above the gum gradually deacetylates. Its stability depends on the gum concentration: the higher the concentration the more stable the solution.

Enzymes commonly present in food products or added to such products (amylase, pectinase, cellulase) do not degrade xanthan gum although it can be partly degraded by endo- β-1,4-glucannases after removal of calcium ions [256].

Interactions and precipitation can occur in acidic and/or heat-treated dairy-protein systems [239].

Oxidizing Agents. Xanthan gum solutions are degraded by high levels of strong oxidants such as hypochlorite, persulfate, and hydrogen peroxide [247], particularly at high temperature. The gum will dissolve in 8 % solutions of sulfuric, nitric and acetic acids, 10 % hydrochloric acid, and 25 % phosphoric acid [257]. Such solutions remain stable for several months.

Solvents. Up to 50 % ethanol and propylene glycol can be added to aqueous xanthan gum solutions without causing precipitation.

Other Hydrocolloids. Xanthan gum is highly compatible with alginates and starch exhibiting long term stability. It is completely compatible with most natural and synthetic thickeners.

Gel Formation. Two models have been proposed for weak gel formation in xanthan gum solutions; both models are based on the occurrence of xanthan molecules in helical structures (Fig. 28). In the model of NORTON et al., single helical regions associate to form a network [258]. The model of MORRIS [259] is based on a double-helical model for xanthan. The primary mechanism is considered to be end-to-end association into fibrous aggregates via double-helix formation.

Xanthan gum interacts with the galactomannans (locust bean, guar, and tara gum) and glucomannans synergistically, leading to enhanced viscosity or gel formation. The formation of thermoreversible gels by synergistic mixtures of xanthan gum with certain galacto- and glucomannans has been ascribed to intermolecular binding through cocrystallization of denatured xanthan chains within the mannan crystallite [260]. The cellulosic backbone of xanthan gum and the stereochemically similar mannan backbone both form ribbonlike structures. The mixed crystallites probably act as strong junction zones to consolidate the weak xanthan gum network.

Gel Formation with Galactonmannans. At all concentrations and blend ratios xanthan gum and *guar gum* interact to produce a synergistic viscosity increase. This interaction will occur in the cold although higher viscosities are generated if the system is heated and cooled.

It is presumed that the interaction occurs between the xanthan gum and the “smooth” regions of the galactomannans, thereby explaining the stronger interaction with locust bean gum than with guar gum [261-263]. Xanthan gum exhibits a similar reactivity with tara gum [35].

The xanthan gum – guar gum interaction leads to an increase in solution viscosity and elastic modulus (*G*'). Determinations of elastic modulus and apparent viscosity are important for the stabilization of emulsions and suspensions (e.g., salad dressing requires a high elastic modulus while sauces and soups need a high apparent viscosity). Maximum viscosity synergism is produced at total gum concentrations of up to 1 %. The synergistic ratio varies with the total gum level; for example, at a total gum level of 0.5 % the maximum viscosity is produced with a ratio of xanthan gum:guar gum of 30 : 70 while at a total gum concentration of 0.2 % the ratio is nearer 50 : 50. The synergism decreases in the presence of ionic materials such as salt and acid. These synergistic blends have a lower elastic modulus which is important in some food applications. The presence of xanthan gum improves the heat stability of guar gum. These blends have a wide variety of applications due to the good sensory properties and lower cost than xanthan gum alone.

In *locust bean gum* the ratio of mannose (backbone) to galactose (side chains) is ca. 4 : 1 but, unlike guar gum, the distribution of the side chains is

more irregular — there are regions that are highly substituted ("hairy") and unsubstituted ("smooth") regions. In xanthan gum – LBG blends at total gum levels of < 0.1 % synergistic viscosity increases are produced; at gum levels > 0.1 % strong cohesive thermoreversible gels exhibiting very little syneresis are obtained. The optimal gum ratios are xanthan gum : LBG of 40 : 60 to 60 : 40. The interaction, as demonstrated by gel strength, is stronger at neutral pH and decreases with decreasing pH. In food products this gel texture by itself is undesirable but it can be modified by the inclusion of starches and/or proteins [239].

Rheological and ultracentrifugation studies were conducted on heated and unheated mixtures of xanthan gum with whole LBG, and temperature fractions of the latter possessing different mannose : galactose ratios [264]. Results suggest that xanthan gum and LBG interact via two distinct mechanisms. One mechanism takes place at room temperature, gives weak elastic gels, and has little dependence upon the galactose content of the galactomannan, whereas the second mechanism requires significant heating of the polysaccharide mixture, gives stronger gels, and is highly dependent upon galactomannan composition [264].

Mixed gels of xanthan gum and galactomannans (guar gum and fractionated LBG) were compared by means of oscillatory shear measurements [265]. Whatever the proportion of LBG, maximal synergism was observed when the ratio of xanthan gum to galactomannan was 1 : 1. However, the magnitude of this maximum varied with LBG content in the mixture.

If guar gum is modified through partial removal of galactose substituents with an α-galactosidase, it also gels with xanthan gum [260]. The sedimentation rate in aqueous mixtures of xanthan gum and enzyme-modified galactomannans (the galactose content being decreased by the enzyme) was studied [266]. Results were related to rheological properties of the systems at large deformations. The shear modulus increased while the strain at yielding and sedimentation velocity decreased with decreasing galactose content of galactomannan. Properties of the xanthan gum enzyme-modified galactomannan system were compared with those of xanthan gum – LBG systems. LBG was suggested to be a better stabilizer than the enzyme-modified galactomannans studied [266].

Gel Formation with Glucomannans. Xanthan gum – konjac mannan (glucomannan) interactions are strong at total gum concentrations above 0.2 % [267]. The optimum ratio is between 40 : 60 and 30 : 70. The presence of salt decreases the interaction. At temperatures > 50 °C, the system's *G*' is higher than its *G*'', indicating well defined elastic properties. At ca. 55 °C the gel structure collapses and there is a sharp decrease in the value of *G*'. At values > 55 °C the behavior is typical of a liquid which has *G*'' significantly higher than *G*'. At ca. 1.0 % total gum concentration, maximum gel strength is achieved, with no further increase in this property with increasing gum concentration. The mechanical properties of xanthan gum – konjac mannan are also similar to those of xanthan gum – LBG.

Others. Small amounts of xanthan gum are sufficient to stabilize *starch solutions* during storage. Xanthan gum at 0.1 – 0.2 % prevents starch solution retrogradation and increases its stability, especially at low pH (around 3). These small amounts of xanthan gum also improve starch stability during freeze – thaw cycles.

Reactions of xanthan gum with specific dextrins and incompatibility between xanthan gum and gum arabic at pH values below 5 have been reported. Xanthan gum also reacts with casein below its isoelectric point [268].

Figure 28. A) Weak gel formation in xanthan gum solutions by self-association of single helices and B) End-to-end association via double-helix formation into fibrous aggregates [260]

11.3. Analysis

The presence of xanthan gum can be indicated by the formation of a gel during cooling of a 1: 1 mixture with carob gum in a 1 % solution. Its presence can also be indicated from the reaction of pyruvate with 2,4-dinitrophenylhydrazone in a hydrolysate.

11.4. Applications, Market

The applications of xanthan gum are based especially on the viscous behavior and stabilizing properties of this hydrocolloid. In industry, xanthan gum is used in groups 18, 19, 26, 27, 28, 29, and 33 (Table 2). These applications enabled Kelco, the first producer of xanthan gum, to carry out a comprehensive toxicological evaluation that resulted, in 1969, in the acceptance of this hydrocolloid in foods, where it has found applications especially in groups 4, 5, 8, and 12.

Xanthan gum is produced by several companies. Present production is estimated at ca. 20 000 t/a. For food applications prices are ca. $ 11 – $ 13 per kilogram. Because of its specific properties the potential for this polysaccharide is great.

[Top of Page]

12. Gellan Gum

Alphons C. J. Voragen and Ian Challen

Gellan gum is produced by the bacterium *Pseudomonas elodea* (ATCC 31461). The bacterium was originally found growing in a lily pond in Pennsylvania, USA. Gellan gum has been approved for food uses [260], [269], [270]. It is a broad-spectrum, multipurpose gelling agent, which is fully compatible with many food systems and processes. Gellan gum is both cold setting and thermosetting; its melting point (thermoreversible and thermoirreversible) depends on ionic strength. Gelled products can be made to be stable or to melt when subjected to retorting and microwave cooking.

Production. The gum is produced commercially by inoculating a fermentation medium with the microorganisms. The medium contains a carbon source, phosphate, organic and inorganic nitrogen salts, and trace elements. The fermentation is carried out under sterile conditions with careful control of aeration, agitation, pH, and temperature [271]. When fermentation is complete, the viscous broth is pasteurized to kill viable bacteria before the gum is recovered. Recovery can be achieved in several ways. Direct recovery yields the gum in its native or *high acyl form*. Treatment of the broth with alkali causes deacylation resulting in the *low acyl version*. The presence of the acyl substituents largely influences the resulting solution properties and gel characteristics [272].

Structure. Gellan gum is a linear anionic polysaccharide with a tetrasaccharide repeating unit:

-3)- β-D-Glc-(1,4)- β-D-GlcA-(1,4)- β-D-Glc-(1,4)- α-L-Rha-(1-

Light scattering and intrinsic viscosity measurements give a molecular mass of approximately 5×10^5 for the deacylated gum [273].

In the native polysaccharide two acyl substituents, L-glycerate and acetate, are present. Both substituents are located on the same 1,3-linked glucosyl residue. The glycerate is esterified on the hydroxyl group on C-2, the acetate on the hydroxyl group on C-6. On average, there is one

glycerate per repeating unit and one acetate per every two repeating units [274].

Chemical analysis established that glycerate substitution predominates over that with acetate [275]. In addition, glycerate substitution dramatically influences gellan gum properties since this bulky substituent hinders chain association and accounts for the change in gel texture brought about by de-esterification [270].

X-ray diffraction studies of oriented fibers [275-277] shows that gellan gum exists as a three-fold, left handed, parallel double helix. The pair of molecules that comprise the helix is stabilized by hydrogen bonds at each carboxylate group. In the potassium salt of the deacylated version the potassium ion is coordinated to the carboxylate group, which, in turn, is involved in interchain hydrogen bonds to stabilize the duplex. In this structure the location of the potassium ions on both the inside and the outside of the helix provides a mechanism for both stabilization of the helix and the association of the helices that is necessary to produce a macromolecular gel structure to aggregate [278]. The calcium salt form fits the same model with the divalent calcium ion replacing the potassium – water – potassium bridge [279]. In these salt forms of the gel, helix aggregation is responsible for the brittle nature of the gel. In the native form the acyl substituents do not prevent helix formation. However, the acetate groups interfere with aggregation, resulting in elastic rather than brittle gels.

Hydration. The pure sodium ion form of gellan gum hydrates at room temperature in deionized water. However, the commercial product is a mixed salt — predominantly in the potassium ion form but also containing other ions such as sodium, calcium, and magnesium. This form is not soluble in cold water since the low level of divalent ions is sufficient to hold the molecular chains together and, thereby, inhibit hydration. Hydration can be achieved by dispersing the gum in deionized water and heating to 75 °C. In tap water, the hydration temperature depends upon the concentration and types of ions in solution. For example, at around 180 ppm calcium carbonate hardness (0.0072 % calcium) the gum will not dissolve even in boiling water but it will hydrate at 90 °C in a 1 % sodium chloride solution [272].

In many systems, hydration of gellan gum by simply dispersing the gum in water and heating is not practical. In such systems hydration is effected by the addition of a sequestrant such as sodium citrate. The sequestrant removes the inhibitory divalent ions from both the gum and the water, but (if used at the appropriate amounts) does not introduce sufficient sodium ions into the system to prevent gum hydration. Depending upon the ions initially present and their concentrations, gellan gum can be hydrated at room temperature when a sequestrant is used [272].

Solution Properties. Highly viscous solutions of *low acyl gellan gum* can be prepared using a sequestrant. At a concentration of 1 wt % gellan gum solutions are less pseudoplastic than xanthan gum solutions but more pseudoplastic than solutions of high molecular mass sodium alginate [276]. A large drop in the solution viscosity of gellan gum is observed at 25 – 40 °C. This reflects a conformational change from some form of relatively ordered, nonaggregated double helix to a random coil. This change is reversible.

Native, or *high acyl gellan gum* dispersions in cold water have very high solution viscosities. Such solutions are very sensitive to salt concentration. In equally concentrated solutions of xanthan gum and gellan gum containing increasing levels of sodium chloride the viscosity of the native gellan gum is strongly dependent upon the salt concentration whereas that of the xanthan gum is not. High acyl gellan gum solutions are highly thixotropic; such behavior is the outcome of gel-like network formation. Similar thixotropic behavior is observed with solutions containing a blend of xanthan gum with locust bean gum.

Gel Formation. Unlike other gums gellan gum forms gels with many ions including hydrogen ion. However, its affinity for each ion is different. Divalent ions have a much stronger affinity than monovalent ones. Divalent ions like calcium and magnesium produce optimal gel strength at 3 % of the level required with sodium and potassium ions [280]. Since ions promote chain association in forming gels, the ion levels needed to cause gelation tend to prevent the gum from hydrating. Furthermore, in keeping with their respective affinities, divalent ions inhibit hydration much more strongly than monovalent ions.

Ions are needed to set up the gel network. The simplest way to make a gellan gum gel is to hydrate the gum in deionized water by heating the gum dispersion to above 75 °C, add ions such as calcium or sodium ions to the hot solution, and cool. When sequestrants are used for hydration, ions are already present in the system. Since the level of these ions is such that they do not prevent hydration, they are also not sufficiently abundant to form strong gels. In several applications such weak gels are quite acceptable but, to optimize gel strength, additional ions must be added. Again, these ions can be added to the hot gellan gum solution which will later gel when allowed to cool.

Gel Texture. The texture of gellan gum and other polysaccharide gels has been investigated using the technique of Texture Profile Analysis on an Instron (a testing machine produced by Instron). Free-standing gel disks were prepared by allowing hot solutions to cool in ring molds. The set, tempered, gels were compressed twice in succession to a given percentage of their original height at a given rate. The textural parameters (modulus, hardness, brittleness, elasticity and cohesiveness) were calculated from the resulting force/deformation curve [272]. The results show that gels made with low acyl gellan gum have a high modulus and are very brittle; in contrast high acyl gellan gum gels are very elastic, nonbrittle and cohesive [281], [282].

Low acyl gellan gum gels are clear, firm to the touch and do not melt, but they release liquid when eaten giving a melt-in-the-mouth sensation. This property is important to flavor release and can be useful in, for example, dessert products [283]. Other investigations have suggested that overall flavor increases as gel hardness decreases and gel brittleness increases [284].

Melting and setting points, which are important gel properties, depend upon ion concentration and type and, to a lesser extent, on gum concentration [269]. Gels differ in their setting temperature. For example, those containing calcium ions set between 25 and 40 °C, and those with sodium ions set at 40 – 50 °C. At lower ion levels, gels remelt upon heating, at higher ion levels they do not melt below 100 °C.

Applications. Gellan gum is used in many applications including microbiological media, tissue culture media, food and pet feeds, photographic emulsions, and microcapsules. It is also used as a model for studying gel swelling and gel shrinkage [269], [285], [286]. Gellan gum can be used as a fining agent for alcoholic beverages including beer, wines, and fortified wines [287].

Gellan gum is mainly used in confectioneries, jams and jellies, fabricated foods, water-based gels, pie fillings and puddings, icings and frostings, and dairy products. Gellan gum and polydextrose were used to produce low-calorie or sugar-free jelly sweets where the final solids content exceeded 80 %. In comparison to other gelling agents gellan gum does not appreciably add to the viscosity of the depositing mix and is, therefore, an ideal gelling agent for such systems [288].

Gellan gum is useful in cocoa and chocolate products [289] and in alcoholic and nonalcoholic beverages [290].

Gellan gum is used in a variety of Japanese food including Mitsumame jelly cubes, soft and hard red bean jelly and Tokoroten noodles [269]. It has been reported to stabilize oil-in-water dispersions [291] and can be used to prepare gels that are dried and subsequently rehydrated to their original shape [292].

Legal Aspects. Gellan gum has been shown to be completely safe for use in food. It has been given a “not specified” ADI by the Joint FAO/WHO Expert Committee on Food Additives [293] and by the EC's Scientific Committee for Food [294].

Gellan gum is approved in over 30 countries worldwide, including the United States, Canada, Australia, South Africa, Japan and most of South East Asia, e.g., Hong Kong, Philippines, Taiwan and Thailand, most of South America, and all 15 EU member states.

In the European Union gellan gum is one of the generally permitted additives listed (as E418) in Appendix I of the European Parliament and Council Directive 95/1/EU on food additives other than colors and sweeteners [295].

Specification and Purity. Kelcogel gellan gum complies with the specifications for gellan gum prepared by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) [296] and the Food Chemicals Codex (FCC) [297].

Market. The commercially available products are K9A50, a nonclarified form of the gum for industrial applications; Kelcogel LT100, a nonclarified form and Kelcogel, a clarified form for food and industrial uses; and Gelrite, which is used for microbiological plating media. All gellan gum is produced by NutraSweet Kelco (a Monsanto company). Gellan gum is priced at about $ 53 per kg.

13. Galactomannans [2-6], [11], [298]

Alphons C. J. Voragen

Galactomannans are plant reserve carbohydrates, like starch, that occur in the endosperm of the seeds of many Leguminoseae. During sprouting, the galactomannans are enzymatically degraded and used as nutrition. Of the many known galactomannans, up to now only three have been processed and used on an industrial scale:

1. **Locust bean gum (carob gum)** has been known for a long time. It is derived from seeds of the carob tree (*Ceratonia siliqua* L.) which grows around the Mediterranean Sea, in Spain, Portugal, and Morocco, where more attention is paid to its systematic cultivation. The annual production is estimated at 10 000 – 12 000 t.
2. **Guar gum** is at present the most important galactomannan. It is derived from the seeds of the guar plant (*Cyamopsis tetragonoloba* L. Taub.), which grows in India and Pakistan. Since 1944, guar plants have also been cultivated on a large scale in the southern United States. They have been introduced into Brazil, Africa, and Australia, where two crops a year can be obtained. The industrial production of guar gum began around 1940. The annual production is estimated at ca. 125 000 t.
3. **Tara gum** has been produced only since the 1970s, to a much lesser degree (1000 t/a), from the seeds of the tara tree (*Cesalpina spinosa* L.), which occurs mainly in Peru.

The galactomannans on the market are flours prepared from the endosperm of the corresponding seeds. The carob and tara kernels are particularly difficult to process because of their tough, hard hulls. Remnants of the hulls and seeds are, therefore, always present in small amounts. The pure polysaccharide extracted from the flour of locust bean gum is often designated carobin gum and the polysaccharide from guar flour, guaran.

13.1. Structure

Galactomannans have a backbone of β-(1,4)-glycosidically linked mannopyranosyl residues. This backbone is substituted with single-unit α-D-galactopyranosyl residues linked to the O-6 of certain mannose moieties. This substitution renders the mannans soluble. Within the various mannans a wide spectrum of chemical structures occurs. This diversity of structure includes not only a wide variation in their mannose: galactose ratio, but also significant differences in the distribution of galactose units along the mannan backbone (Fig. 29) [299], [300]. For *locust bean gum* a mannose: galactose ratio of 3.5 has been established, compared to a ratio of 3 for *tara gum* and 1.5 for *guar gum*. A measure of the differences in the distribution of galactose side groups has been obtained from an examination of the degree of hydrolysis and the characteristic array of oligosaccharides obtained by digestion with an endomannanase. In this way, DEA et al. [301] established that a *tara gum* has a more statistically random distribution of side chains while *locust bean gum* has a nonregular, nonstatistically random distribution with a certain proportion of unsubstituted blocks of intermediate length. *Guar gum* was found to have few, if any, regions that were unsubstituted (smooth regions) with galactose. Galactomannans differ further in their molar mass distribution; the highest values were established for guar gum. These differences in fine structure between the galactomannans, involving the extent and pattern of galactosyl substitution and molar mass distribution, account for their very different functional properties.

Figure 29. Structural features of galactomannans

13.2. Production [4], [11], [298]

Guar Gum. For the separation of the germ and the endosperm halves, guar seeds are first screened to remove foreign matter and then fed to an attrition mill to split the seeds in two endosperm halves; finally, the germ material is sifted off. Despite their relatively low galactomannan content the remaining endosperm halves, covered with hull (splits), are suitable for many technical applications. For higher-quality demands, and particularly for food applications, the endosperm must be further purified and liberated from the adhering hull. Various processes are used for this; in general, the splits are treated with moist or dry, hot air, which results in the loosening of the hull as a result of different swelling properties. After removal of the hull by sifting, pure endosperm is obtained with a galactomannan content of 85 – 95 % based on dry matter. By suitable milling and screening techniques the endosperm can be worked up to the desired commercial products.

Locust Bean and Tara Gum. Since the hull of carob and tara gum is very hard and tough, these gums are difficult to process. For removal of the hulls, two different processes exist. In the *acid process* the hulls are carbonized by treating the kernels with moderately dilute sulfuric acid at elevated temperature. Similar to the guar gum process, the remaining hull fragments are then removed by washing and brushing operations. After a drying step the dehulled kernels are cracked and the germs sifted off from the endosperm. Commercial products are obtained by milling and screening.

In the vanishing *roasting process* the kernels are roasted in a rotating furnace, where the hulls pop. The endosperm is then obtained as described above. This process yields products of somewhat darker color. However, the use of sulfuric acid is avoided.

13.3. Properties

The most prominent properties of galactomannans are their high water-binding capacity, their potential to form highly viscous solutions even at low concentrations, and the interaction of locust bean gum with carrageenans, agar, and xanthan gum. In double logarithmic plots of zero shear viscosity versus concentration multiplied by intrinsic viscosity, galactomannans exhibit a different type of viscosity behavior from most polysaccharides for which nonspecific physical entanglement between fluctuating random coil molecules is the underlying mechanism. Galactomannans show an earlier onset of concentrated solution behavior and a substantially greater concentration dependence thereafter [299], [300]. This behavior is attributed to the occurrence of interchain associations inherent to β-1,4-D-mannan chain segments. Such self-association has also been observed for β-1,4-D-glucan and β-1,4-D-xylan structures.

Locust bean gum and guar gum are both *water soluble*; they differ, however, in their dissolution behavior. Whereas guar gum is readily soluble in cold water, locust bean gum can be solubilized only by boiling. Solutions of both galactomannans are, depending on their purity, somewhat cloudy because of the presence of some proteins and crude fiber.

Even 1 wt % solutions are highly *viscous* (2000 – 6000 mPa · s, measured with an RTV Brookfield viscometer at 20 rpm); 2 – 5 wt % swollen dispersions show gellike behavior. The viscosity of solutions is hardly influenced by ionic strength. Locust bean gum solutions can gel at high

sodium hydroxide concentrations. Also boric acid and alkaline copper salt solutions cause flocculation or gelling of the galactomannans. Mixing of solutions of locust bean gum and xanthan gum results in an increase of the viscosity or even in gel formation (after boiling [209]). Such synergistic interactions have also been observed for combinations of locust bean gum with carrageenan or agar (Section Production). Dilute galactomannan solutions form elastic, transparent films upon dehydration.

Galactomannans are rapidly *degraded* in acidic, aqueous solutions at elevated temperature, resulting in a rapid loss of viscosity. They can also be degraded by oxidants and by microbial enzymes (mannanases); under alkaline conditions, they are rather stable [302]. When stored for longer periods of time, solutions of galactomannans must therefore be protected against microbial degradation by addition of preservatives.

13.4. Analysis and Composition of Commercial Preparations

Commercial galactomannan preparations still may contain remnants of germs and hull that are rich in protein and fiber, and reduce the galactomannan content. The galactomannan content is therefore an important factor in quality. This *gum content* is determined by analyzing the impurities and subtracting their total from 100 %. Depending on the application, products with different galactomannan content are used.

Another quality factor is the *viscosity* of the aqueous solution, usually measured in 1 wt % systems. Locust bean gum must first be solubilized by heating.

The *presence of galactomannans* can be demonstrated by various precipitation reactions (e.g., gelation with borax). For determination of the *mannose : galactose ratio*, the preparation is hydrolyzed and the sugar moieties are analzyed by using gas chromatography [15], [29].

13.5. Derivatives

As with cellulose, galactomannans contain primary and secondary hydroxyl groups, which, in principle, can be derivatized and substituted like cellulose. Only hydroxyalkyl, carboxymethyl, and cationic derivatives, as well as partially depolymerized products, are of industrial significance, however.

Hydroxyalkyl derivatives are obtained by treating galactomannans with ethylene or propylene oxide in an alkaline medium. These derivatives differ from the parent material by having a faster rate of hydration and being almost completely soluble.

Carboxymethylated products are obtained by “etherification” of a certain portion of the hydroxyl groups with monochloric acid or sodium monochloroacetate. Unlike carboxymethyl celluloses, which are soluble only at degrees of substitution in the range of 0.7 – 1.0, galactomannans — if not already soluble prior to derivatization — become completely soluble at a degree of substitution of <0.05.

Cationic derivatives are obtained by treatment of galactomannans with suitable reactive organic amines such as 2-hydroxy-3-chloropropyltrimethylammonium chloride or its reaction product 2,3-epoxypropyltrimethylammonium chloride, which forms in alkaline medium.

Partially depolymerized galactomannans with reduced viscosities are obtained by oxidative, hydrolytic (acid), or enzymatic degradation. Conversely, by reaction with bifunctional molecules such as epichlorohydrin, *cross-linked galactomannans* can be obtained, which — depending on their degree of cross-linking — are only partly water soluble or fully insoluble. Plant α-galactosidase that can remove galactose from galactomannans has been cloned in yeast and can be produced conveniently. This enzyme is active in systems containing up to 35 % galactomannan [303].

13.6. Applications

Guar gum has found application in many industries; its use is still increasing. Most uses are based on its good solubility in water and the high viscosity of aqueous solutions. In many applications, its inertness against high concentrations of salts of monovalent cations, its ability to form gels with certain multivalent cations, and its flocculating action are also decisive. *Derivatives of guar gum* are used in the oil industry in secondary or tertiary oil recovery of nearly exhausted oil wells. For applications in the textile industry (Table 2, groups 30 and 31), a variety of native and derivatized types are produced. They are also used in the manufacture of paper (group 29), explosives (group 26), and cables. In the latter applications, guar gum is added in advance to immobilize the inevitably penetrating water. They are also used in the pharmaceutical industry and as flocculating agents in the processing of minerals and effluent purification (group 32). In the food industry, guar gums are used as efficient thickeners of aqueous systems, thereby controlling the mobilization of water. This influences the consistency, body, and shelf life of aqueous food systems, as well as the stability of oil – water and water – oil emulsions. They are used in groups 3, 5, 6, 8, 9, and 12, and have also found application in pet food (group 13) and cattle feed.

Due to its higher price, *locust bean gum* is used mainly in the food industry, in the same groups as the guar gums. Of special interest for locust bean gum is its synergistic action with other hydrocolloids such as carrageenans, agar, and xanthan gum.

13.7. Market

Of the 125 000 t of *guar gum* produced annually, ca. one-third is used in the food industry; the remainder has found technical application. *Locust bean gum* is used almost completely in the food and pet food industry. The prices on the world market average ca. $ 1.1 – $ 1.3 per kilogram for guar gum and $ 6.4 – $ 7.5 per kilogram for locust bean gum.

Poly(Vinyl Esters)

General aspects of polymers, properties and testing, processing, additives, and analysis are discussed in Plastics, General Survey; Plastics, Properties and Testing; Plastics, Processing; Plastics, Additives; and Plastics, Analysis, respectively. States of Order are treated in Plastics, Properties and Testing. Fundamental aspects of polymerization reactions are treated in Polymerization Processes.

1. Introduction

Poly(vinyl esters) are polymers with structural units of the general formula:

They are synthesized by polymerization of vinyl ester monomers $CH_2{=}CH{-}O{-}CO{-}R$.

In addition to vinyl ester homopolymers, co- and terpolymers of mixed vinyl esters or of vinyl esters and other comonomers are also important industrially.

Poly(vinyl acetate) and vinyl acetate copolymers are the most important poly(vinyl esters).

In 1912 and 1913 KLATTE synthesized the first poly(vinyl esters): poly(vinyl chloroacetate) ($R = CH_2Cl$) and poly(vinyl acetate) ($R = CH_3$) [1].

2. Raw Materials

Vinyl Esters. Vinyl acetate is predominantly produced by acetoxylation of ethylene with acetic acid on palladium catalysts. Vinyl esters of $\geq C_3$ acids are produced by addition of acetylene to the acid, or by palladium- or mercury-catalyzed transvinylation of vinyl acetate (see → Vinyl Esters).

On an industrial scale vinyl acetate ($R = CH_3$), vinyl propionate ($R = CH_2CH_3$), vinyl pivalate [$R = C(CH_3)_3$], vinyl 2-ethylhexanoate [$R = CH(C_2H_5)-(CH_2)_3CH_3$], vinyl laurate [$R = (CH_2)_{10}CH_3$], VeoVa 10 [$R = C(CH_3)R'_2$] and VeoVa 9 [$R = C(CH_3)R'_2$] are used for the production of polymers. VeoVa 9 and VeoVa 10 are the vinyl esters of versatic acids – synthetic tertiary carboxylic acids with nine or ten carbon atoms (see → Carboxylic Acids, Aliphatic, Chap. 10.). Previously, vinyl chloroacetate, vinyl isobutyrate, vinyl caproate, vinyl isononanate, vinyl stearate, VeoVa 911, and vinyl benzoate were also used in industry for a time or were envisaged for this purpose.

Data for the industrially most important monomers are summarized in Table 1. High-purity monomers are required for the reproducible production of polymers. The content of other components can be determined by gas chromatography. The purity determination of vinyl acetate is standardized in ASTM standards [2]. Impurities which are particularly disruptive are those which severely inhibit polymerization, such as crotonaldehyde and vinylacetylene, or compounds that act as chain-transfer agents, such as acetic acid, acetaldehyde, acetone, benzene, or toluene [3], [4]. Impurities with two readily copolymerizable double bonds,

such as vinyl crotonate, also cause problems because they can lead to cross-linking reactions and thus to the formation of insoluble polymers. Monomers used for emulsion polymerization must be completely free from previously formed polymer.

To prevent polymerization during storage and transport, 3 – 20 ppm of a phenolic compound such as hydroquinone or hydroquinone monomethyl ether is used as an inhibitor. The inhibitors generally need not to be removed before polymerization, since they can be rendered inactive during polymerization by using a sufficiently large amount of initiator.

To assess the purity and the suitability for polymer production, particularly in the case of vinyl acetate, a simple polymerization test [5] is used. A given quantity of monomer is warmed with 0.5 % benzoyl peroxide (relative to monomer) to 70 °C under defined conditions, and the time elapsing until the start of polymerization is recorded. The delay in comparison with pure, inhibitor-free monomer is a measure of the impurity content or of the amount of inhibitor added for stabilization.

Initiators. In industrial poly(vinyl ester) processes polymerization is initiated by radical

initiators. Other processes, such as photopolymerization, radiation-induced polymerization, and the use of organometallic compounds as initiators have not achieved importance.

Azo compounds (e.g., azobisisobutyronitrile), diacyl peroxides (e.g., dibenzoyl peroxide and dilauryl peroxide), peroxyesters (e.g., *tert*-butyl peroxybenzoate and *tert*-butyl peroxyoctanoate), hydroperoxides (e.g., *tert*-butyl hydroperoxide and cumene hydroperoxide), and water-soluble inorganic peroxides (e.g., hydrogen peroxide, potassium, ammonium, or sodium peroxodisulfate) are used as radical initiators. Redox systems are also widely used, in which a peroxy compound is combined with a reducing agent (e.g., H_2O_2–ascorbic acid; H_2O_2–Fe^{2+}, ammonium peroxodisulfate – sodium sulfite, or *tert*-butyl hydroperoxide – sodium formaldehyde sulfoxalate) [6].

Initiators are chosen according to their solubility in the solvent or monomer, and the decomposition half-life of the substance or the redox combination under polymerization conditions.

Sufficient initiator must be used to oxidize any inhibitors present in the monomer, and to ensure a constant reaction rate in spite of continuous decomposition of the peroxide under the reaction conditions. High radical concentrations result in polymers of low molecular mass. Generally 0.1 – 1 % of an initiator based on the monomer is used. The initiator can be added at the start of the polymerization in one portion or added gradually during the course of the reaction.

Molecular Mass Regulators. To regulate the molecular mass of the polymer, C_1–C_4 alcohols, C_2–C_4 aldehydes, thiols ($>C_{10}$), or chlorinated hydrocarbons (e.g., carbon tetrachloride) are used; for chain-transfer constants, see [7].

3. Polymer Structure

The kinetics of homo- and copolymerization of vinyl esters has been widely studied; for a summary, see [3]. Three features are particularly characteristic of the polymerization of vinyl acetate:

1) Very high reactivity of the vinyl acetate radical
2) Relatively low reactivity of vinyl acetate monomer towards attack by radicals
3) High chain-transfer constants of vinyl acetate, poly(vinyl acetate), and other polymers relative to the vinyl acetate radical or the growing chain

The differing reactivity of the radical and the monomer, which is also the case for other vinyl esters, makes the production of uniform copolymers from vinyl esters with comonomers that behave differently (e.g., where the monomer reacts more rapidly with radicals) difficult. For copolymerization parameters *r*, *q*, and *e*, see [7]. Chain-transfer reactions involving the monomer or the polymer results in products with a high degree of branching being formed in the polymerization of vinyl acetate. Three types of branching are observed in the final polymer:

The side chains can be bound to the main chain via an ester group (a) and also directly by a C–C bond (b and c). In the case of chain-transfer in (a), the side chains can be cleaved hydrolytically. The extent of side chain formation at positions (a), (b), and (c) depends strongly on the reaction conditions. The data vary between 97 % and 75 % for (a) [8–10]. The lowering of the average degree of polymerization occurring on saponification of polyvinylacetate, the reduction in the number of side chains in the polymer, and the broadening of the molecular mass distribution, which depends on the proportion of (a) branches, must be taken into consideration in the production of downstream products of poly(vinyl acetate) (see → Polyvinyl Compounds, Others).

In poly(vinyl acetate) the monomer units are linked predominantly head-to-tail. The proportion of head-to-head segments decreases with decreasing polymerization temperature [3].

4. Production

Homo- and copolymers of vinyl esters are produced both in the homogeneous phase by bulk or solution polymerization, and in the heterogeneous phase by suspension and emulsion polymerization.

4.1. Bulk Polymerization

Bulk polymerization can be carried out discontinuously by monomer addition in stirred reactors or continuously in tubular reactors. The monomers are heated to the reaction temperature in the presence of monomer-soluble initiators. The heat of reaction can be removed for low-boiling monomers by a reflux condenser, and in all other cases through the reactor wall. The process is limited to polymers with low to medium molecular mass. Molecular mass and melt viscosity must be sufficiently low at the end of the reaction that the product can be removed from the reactor without difficulty.

Discontinuous processes for poly(vinyl acetate) with a molecular mass of $M_w = 35\,000$ have been described. The molecular mass can be controlled by addition of regulators [11]. A similar process is used for the production of graft copolymers from poly(ethylene glycol) and vinyl acetate [12].

Poly(vinyl acetate) with $M_w = 300\,000$ is obtained in tubular reactors, which give almost quantitative polymerization [11].

Terpolymers can be produced from VeoVa 10, styrene, and maleic or acrylic esters by substance polymerization at 155 – 170 °C [13]. Vinyl acetate – ethylene copolymers with an ethylene content of $> 60\,\%$ are produced by using the high-pressure polyethylene process (see → Polyolefins, Chap. 1.5.1.3.).

4.2. Solution Polymerization

Solution polymerization allows the production of polymers with a more uniform structure and lower degree of branching in a simpler process. The removal of the heat of reaction is less problematic than in bulk polymerization, since the reaction can be carried out under reflux at the boiling point of the solvent or one of the monomers. The degree of polymerization depends on the nature and amount of solvent [14].

A process which allows the production of relatively uniform, high molecular mass poly(vinyl acetate) is solution polymerization with relatively low conversion. The unreacted vinyl acetate acts as an additional solvent. The reaction is stopped at a conversion of, for example, 50 % by adding an inhibitor, and unreacted monomer is removed.

Poly(vinyl acetate) which is to be further processed to poly(vinyl alcohol) [7], is generally produced in methanolic solution. Use of *tert*-butanol permits the production of high molecular mass solution polymers because of its low chain-transfer constants relative to the vinyl acetate radical. This is exploited industrially in the production of vinyl acetate – ethylene copolymers with an ethylene content of 50 – 70 % (see → Rubber, Synthetic). Solution polymerization can be carried out as a discontinuous process in simple stirred reactors, which operate under pressure (for vinyl acetate – ethylene) or pressureless, depending on the monomer used and the reaction conditions; or continuously in a tubular reactor or a cascade of stirred reactors, which are particularly suitable for this process.

4.3. Suspension (Bead) Polymerization

In suspension polymerization the monomer, usually vinyl acetate, is suspended in water by stirring together with a monomer-soluble initiator, and heated to the boiling point of the vinyl acetate – water azeotrope for polymerization. The polymer is produced as beads (diameter ca. 0.2 – 3 mm) and can easily be separated after cooling, and dried. Suspension polymerization combines the advantages of bulk and solution polymerizations: heat removal during polymerization is straightforward, and the product can be easily isolated and handled, and is free of solvent. Suspending agents are used to stabilize the two-phase system of water and the monomer or the solution of polymer formed in the monomer during the reaction. In the older literature a large number of active substances are described, including neutral electrolytes such as phosphates, water-soluble polymers such as modified starch, poly(vinyl alcohol), polyacrylamide, polyvinylpyrrolidone, copolymers with

carboxyl groups such as styrene – maleic acid copolymers [11], or crotonic acid – vinyl acetate copolymers.

Apart from the nature of the suspending agent, the shape of the reactor, the stirrer speed, and the stirrer geometry significantly affect the stability of the system and the particle size distribution of the beads formed.

4.4. Emulsion Polymerization

Emulsion polymerization is the most important process for the production of vinyl ester homo- and copolymers. The emulsions, which contain water as the continuous and the polymers as the dispersed phase, are mainly used in the liquid form. Smaller amounts are converted to the polymer by spray-drying to give a powder which can be redispersed in water.

The properties of the product are determined not only by polymer composition and structure, but also by the stabilizing additives used in production, and by the particle size and particle size distribution of the dispersed polymer phase.

In the production of poly(vinyl ester) emulsions three types of stabilizer are used:

1) Water-soluble, polymeric protective colloids, such as poly(vinyl alcohol) [15], [16], [17], hydroxyethyl cellulose, polyvinylpyrrolidone [18], poly(*N*-vinylamides) [19], or starch.
2) Anionic emulsifiers that contain hydrophilic groups such as $-SO_3^-$, $-OSO_3^-$, $-(OCH_2-CH_2)_n-SO_3^-$, or $-OPO_3^{2-}$, in addition to a hydrophobic group. The hydrophobic part of the molecule can consist of $C_{12}-C_{24}$ alkyl or alkylaryl groups,

Typical compounds of this type are dodecylbenzenesulfonate, sodium laurylsulfate, and dioctyl sulfosuccinate. Ethylene sulfonate is an anionic stabilizer [20] that leads to formation of high molecular mass polymers with $-SO_3Na$ groups by incorporation into the polymer.

3) Nonionic emulsifiers with hydrophobic groups and polyether chains as hydrophilic groups. Oxyethylation products of nonylphenol, isooctylphenol, $C_{12}-C_{18}$ fatty alcohols, or low molecular mass poly(propylene oxide) are most widely used. The degree of oxyethylation is 4 – 50.

Protective colloids usually give emulsions with an average particle size of ca. 1 – 10 µm. Ionic emulsifiers give an average particle diameter of 0.1 – 0.3 µm. With a combination of the two types the average particle diameter is ca. 0.2 –2 µm.

The choice of emulsifiers or protective colloids depends on the desired properties of the emulsions. There is a range of known relationships between the emulsifier/protective colloid system, the amount of emulsifier or protective colloid, the polymerization reaction conditions, and the polymer properties [7], [21], [22]. However, they have not yet led to a general theory for the choice of emulsifiers and protective colloids. Therefore, for the production of new poly(vinyl ester) emulsions the most favorable emulsifiers and protective colloids and the optimal concentration must be determined experimentally.

The protective colloid most thoroughly investigated and most often used is poly(vinyl alcohol). Its emulsifying action is strongly dependent on the content of residual acetyl groups. It decreases with decreasing acetyl group content, as does the reaction rate of the emulsion polymerization [23]. Poly(vinyl alcohols) with a residual acetyl content of 0 – 12 % are generally used for the emulsion polymerization of vinyl esters. During polymerization, part of the poly(vinyl acetate) is grafted on to the poly(vinyl alcohol). In peroxodisulfate-initiated polymerization, the content of graft polymer increases with increasing molecular mass and increasing acetyl group content of the poly(vinyl alcohol) [24]. It is also strongly dependent on the initiator. With H_2O_2 and azobisisobutyronitrile as initiators significantly less graft polymer is formed.

Kinetic investigations of the emulsion polymerization of vinyl esters are mainly concerned with vinyl acetate homo- and copolymerization in the presence of ionic emulsifiers [3], [25]. Because of the considerable water solubility of the monomer, in the case of vinyl acetate a mechanism of particle formation differing from that in

the emulsion polymerization of other monomers has been discussed. It is assumed that polymerization initially takes place in aqueous solution since the rate is almost independent of the emulsifier concentration [7], [25–27]. In contrast, experiments on emulsion polymerization of water-insoluble vinyl esters of long- chain carboxylic acids have shown, that here the behavior is similar to that of other hydrophobic monomers such as styrene.

For emulsion polymerization with protective colloids ideas about the stabilizing effect are mainly qualitative. It is assumed that high molecular mass hydrophilic protective colloids are adsorbed as loops on the surface of the particles and stabilize them by forming a hydrate layer.

Discontinuous Polymerization. On an industrial scale, discontinuous emulsion processes predominate. In batch processes the total quantity of monomer is heated to the polymerization temperature with the aqueous solution of the protective colloid or emulsifier and the initiator required to form the final emulsion. In the addition process the monomer or, in the production of copolymers, a monomer mixture is added to the total aqueous phase during the course of polymerization. A special case of the addition process is the preemulsion technique, in which part of the aqueous phase is charged to the reactor and a preemulsion is formed from the other part and the monomer. This preemulsion is then added during the course of polymerization.

After polymerization is complete, the emulsion formed is cooled, treated if necessary with stabilizing additives, plasticizers, or by pH adjustment, and then removed from the reactor. The treatment can also be carried out in additional stirred vessels connected to the reactor.

In the discontinuous processes stirred vessels are used. The stirrer geometry and speed have a major influence on the quality of the emulsion. Anchor stirrers, propellers, impellers, and MIG stirrers are used. In the case of vinyl acetate homo- and copolymers produced at atmospheric pressure, the heat of reaction can be removed by a reflux condenser. For other vinyl esters, and for polymerization of vinyl acetate below its boiling point, jacket cooling or the use of internal or external heat exchangers is necessary.

If low-boiling or gaseous monomers such as ethylene or vinyl chloride are copolymerized with vinyl esters, stirred autoclaves must be used. The amount of ethylene which is copolymerized mainly depends on the ethylene pressure above the reaction medium but also on other process parameters such as reaction temperature and monomer concentration during polymerization [28], [29]. Addition processes [30] and batch processes [31] at ethylene pressures up to 100 bar have been described.

Continuous Processes. For the continuous production of poly(vinyl ester) emulsions, both atmospheric-pressure, and pressurized-vessel processes (for copolymerization with ethylene [32] or vinyl chloride) have been described. The monomers, initiators, emulsifiers and protective colloids, and water are fed, either together as a preemulsion or separately as aqueous and organic phases, to a tubular reactor [33], [34], a stirred-tank cascade, a continuous stirred-tank reactor, or a loop reactor with a circulating pump [35].

Construction Materials. Vinyl esters, poly (vinyl esters), and the additives and initiators used in their production are not very corrosive. To produce poly(vinyl esters) reactors made of stainless steel or glass-lined steel are used. For parts of the plant which only come into contact with the monomers, such as pipes and heat exchangers, aluminum can also be used. Copper and copper alloys should be avoided, since copper ions can inhibit polymerization even at very low concentrations [3].

5. Industrially Important Poly(Vinyl Esters)

The only industrially important homopolymers are poly(vinyl acetate) and, to a much lesser extent, poly(vinyl propionate). All vinyl esters which are accessible on an industrial scale are also used to prepare a large number of co- and terpolymers by combination with one another and with other monomers. In this group vinyl acetate is also by far the most important vinyl ester.

In the following the most important processes for the production of the individual polymers are denoted by letters as follows:

(B) Bulk polymerization
(S) Solution polymerization
(BS) Bead suspension polymerization
(G) Graft polymerization
(E) Emulsion polymerization

Polymers are produced from the following monomers by the methods shown:

Vinyl acetate (B, S, BS, E)
Vinyl acetate – dibutyl maleate (B, E) [36]
Vinyl acetate – *n*-butyl acrylate (E)
Vinyl acetate – 2-ethylhexyl acrylate (E)
Vinyl acetate – *n*-butyl acrylate – *N*-hydroxymethylacrylamide (E) [37]
Vinyl acetate – crotonic acid (S, E) [38]
Vinyl acetate – VeoVa 10 (B, E) [13]
Vinyl acetate – VeoVa 10 – acrylic acid (E) [13]
Vinyl acetate – VeoVa 10 – *n*-butyl acrylate (E)
Vinyl acetate – *N*-hydroxymethylacrylamide (E)
Vinyl acetate – vinyl laurate (B, E) [39]
Vinyl acetate – vinyl laurate – vinyl chloride (E) [40]
Vinyl acetate – ethylene (B, S, E)
Vinyl acetate – ethylene – vinyl chloride (E) [41]
Vinyl acetate – ethylene – acrylic ester (E)
Vinyl acetate – ethylene – acrylamide (E) [42]
Vinyl acetate – ethylene – *N*-hydroxymethylacrylamide (E) [43]
Vinyl acetate – crotonic acid grafted on polyglycol (G) [12]
Vinyl acetate – *N*-vinylpyrrolidone (S)
Vinyl propionate (E)
Vinyl propionate – vinyl chloride (E)
Vinyl propionate – *tert*-butyl acrylate (E)
VeoVa 10 – vinyl chloride (E) [22]
VeoVa 10 – styrene – acrylic ester and/or maleate (B) [13]
VeoVa 10 – VeoVa 9 – methyl methacrylate – butyl acrylate (E)

VeoVa 10 can be completely or partly replaced by VeoVa 9 to achieve special properties.

6. Properties

Poly(Vinyl Acetate) Homopolymers. Poly (vinyl acetate) is amorphous, odorless, tasteless, and has high lightfastness, and weather resistance. The glass transition temperature (T_g = 28 °C) depends to a certain extent on the molecular mass [7]. For electrical, mechanical, and thermal properties, see [7]. The polymers are soluble in many esters, ketones, cyclic ethers, phenols, halogenated aliphatic hydrocarbons, methanol, 95 % ethanol, and 90 % isopropanol.

Commercial poly(vinyl acetate) emulsions with poly(vinyl alcohol) as the protective colloid usually have a particle size of ca. 1 – 10 µm, a solids content of 40 – 65 %, and a viscosity range of 1 – 50 Pa · s. The latex particles are frequently aggregated to produce grape-like formations [44].

Emulsifier-containing homopolymer emulsions, some of which contain protective colloids such as hydroxyethyl cellulose, have lower particle size (0.1 – 2 µm).

The minimum film formation temperature of homopolymer emulsions, which is important for their applications, is 15 – 18 °C. Therefore, for many uses plasticizers, such as dibutyl phthalate, tricresyl phosphate, or auxiliary film formers, are added.

Coarse-particle emulsions stabilized with poly(vinyl alcohol) are mainly important as wood glues and adhesives. Fine- and medium-particle emulsions stabilized by emulsifiers are mainly used as binders for emulsion paints and textiles.

Vinyl Acetate Copolymers. The facile alkaline saponification of the ester groups in vinyl acetate homopolymers is a disadvantage in many applications, since the saponification products are hydrophilic and water sensitive. This low resistance to hydrolysis is one reason for combination with comonomers. The second is the glass transition temperature of 28 °C, which is too high for many uses (e.g., paints and adhesives) and renders the poly(vinyl acetate) too hard and inflexible at the usual temperatures of use. The glass transition temperature can be adjusted by the addition of plasticizers. However, for use where plasticizers are undesirable and increased resistance to saponi- fication is required, soften-

ing comonomers are used, e.g., dibutyl maleate; *n*-butyl acrylate; 2-ethylhexyl acrylate; ethylene; or ethylene in combination with vinyl chloride, VeoVa 10, or vinyl laurate. The glass transition temperature is most effectively lowered by ethylene, vinyl laurate, and acrylic esters, while the resistance to alkali is best improved by ethylene, or ethylene combined with vinyl chloride or by VeoVa 10. Copolymerization with > 20 wt % VeoVa 9 increases the glass transition temperature and the resistance to alkali.

Since for a particular application of a copolymer, a narrow range for the glass transition temperature or for the minimum film formation temperature is required, the ratio of vinyl acetate to the comonomers can only be varied within certain limits. The additional use of VeoVa 9 in the pressureless production of emulsions or the additional use of vinyl chloride for high-pressure polymers allows the production of polymers with a desired glass transition temperature but different vinyl acetate contents. For the evaluation of a copolymer it is critical that, at a monomer ratio required by the glass transition temperature, the other properties are favorable. For example, emulsions used as binders in paints must be stable towards alkalies. LINDEMANN [28] has determined the compositions necessary to achieve glass transition temperatures of + 10 °C, 0 °C, and− 10 °C for the most important comonomers used in the production of vinyl acetate copolymers. Saponification experiments on vinyl acetate copolymers have shown that vinyl acetate – ethylene, vinyl acetate – ethylene – vinyl chloride, vinyl acetate – VeoVa 10, and vinyl acetate – vinyl laurate – vinyl chloride, co- and terpolymers with 50 – 80 % vinyl acetate have particularly favorable properties for paints [41], [45–47]. Use of *N*-hydroxymethylacrylamide allows the production of cross-linkable vinyl acetate copolymers, and the use of crotonic acid gives water-soluble vinyl acetate copolymers with good film-forming properties.

Vinyl Proprionate Homopolymers. Poly(vinyl propionate) differs from poly(vinyl acetate) in its lower glass transition temperature (T_g − 7 °C) and its higher stability towards alkalies [47]. Under the same conditions vinyl propionate polymerizes more slowly than vinyl acetate and gives products with lower molecular mass [48]. Poly(vinyl propionate) is produced industrially by emulsion polymerization.

Vinyl Propionate Copolymers. For many applications the glass transition temperature of poly(vinyl propionate) is too low. To obtain industrially more desirable polymer properties (e.g., T_g, resistance to saponification, weather resistance) it is therefore more commonly used together with comonomers that raise the glass transition temperature. Vinyl propionate – vinyl chloride and vinyl propionate – *tert*-butyl acrylate copolymers are produced by emulsion polymerization. Coatings made from these polymers are relatively resistant to saponification and have good weather resistance.

VeoVa 10 and VeoVa 9 Polymers. Homopolymers of VeoVa 10 or VeoVa 9 have not yet achieved any importance. Copolymers with vinyl acetate (see above) and vinyl acetate and acrylic esters are the most important. A range of other co- and terpolymers have been described [13], [22]. VeoVa 10 – vinyl chloride copolymers in the ratio 2 : 1 to 1 : 2 can be produced by emulsion polymerization in stirred autoclaves. The polymers are very weather resistant and have a high pigment-binding capacity.

Styrene – VeoVa 10 – acrylic ester or maleic ester terpolymers are clear, colorless, saponification resistant, and, on copolymerization with monomers with functional groups, cross-linkable [49].

7. Quality Specifications, Trade Names, Storage and Transport, Wastewater

Quality Specifications. The applications of vinyl ester homo- and copolymers are so varied that uniform, generally valid quality specifications cannot be defined.

The content of unpolymerized monomers, which is generally < 0.5 % can be determined by GC [50], [51]. Molecular mass can be determined by light scattering or gel permeation chromatography.

For emulsions the determination of dry residue (ISO 1625), sieve residue (ISO 4576), pH value (ISO 1148), viscosity (ISO 3219 and ISO 2555), freeze/thaw resistance (ISO 1147),

density (ISO 8962), minimum film formation temperature, and the white point (ISO 2115) is standardized. The size of the latex particles is determined by optical or electron microscopy, by light scattering [52], by the Marshall method [53], or by aerosol spectroscopy [54]. In Germany, for polymers subject to foodstuffs regulations, the chewing gum regulation [55], the cheese regulation [56], and Recommendation XIV [57] apply.

Trade Names and Producers. Airflex (Air Products); Appretan, Mowilith, Mowiton, Imperon-Binder (Hoechst); Emultex (Harlow Chemical Comp.); Everflex (Grace); Propiofan (BASF); Rhodopas (Rhone Poulenc Polymers); Uramul (DSM); Vinamul (Vinyl Products); Ucar (UCC); Vinavil (Montedison); Vinnapas, Vipolit (Wacker).

Storage and Transport. Poly(vinyl esters) are combustible, but not readily flammable. They are generally not corrosive.

For poly(vinyl ester) emulsions, transport and storage containers must be resistant towards the aqueous phase, including low molecular mass substances dissolved therein. Irreversible damage to emulsions can arise through external effects which change the composition or the state of colloidal distribution. For example water loss can result in skin formation on the surface.

Many emulsions are frost resistant. However some products coagulate when the aqueous phase freezes. Producers generally give information on the frost resistance of emulsions.

Undesired aggregation or coagulation of the latex particles can occur on strong shearing in unsuitable pumps or in spray nozzles.

Poly(vinyl ester) emulsions must frequently be protected against attack by microorganisms [58].

Wastewater. With the exception of the less widely used crotonic acid copolymers, the polymers are insoluble in water. They can, however, enter the wastewater system as emulsions. Poly(vinyl esters) are nontoxic but are degraded extremely slowly in water. Emulsions therefore must not be discharged directly into receiving waters. Wastewater that contains emulsion can generally be treated in biological sewage treatment plants. The polymer enters the sewage sludge.

8. Uses, Toxicology, and Economic Aspects

Uses. The most important uses of poly(vinyl esters) are in emulsion paints (→ Paints and Coatings, Chap. 2.4.4.→ Paints and Coatings, Chap. 2.4.5.) and adhesives (→ Adhesives.). Other uses include antinoise compounds, chewing gum bases, concrete additives, soil stabilization, glass fiber sizing material, binders for nonwoven fabrics, fibrous leather substitute, pigment printing pastes, coatings for undersides of carpets, cheese rinds, and coatings for paper.

For some uses (building, adhesives, paints) dispersion powders, which can be redispersed in water before use, are produced from the emul-sions by spray drying [59]. Here vinyl acetate homopolymers, copolymers of vinyl acetate with ethylene, VeoVa 10, or with VeoVa 10 and acrylic esters stabilized with poly(vinyl alcohol) are predominantly used. The main advantage of these products lies in their ability to be stored without any problem, and that they can be combined with hydraulic binding agents as one- component systems [60].

Toxicology. A differentiation must be made between the polymers themselves and the other substances always present in the industrial products. All investigations published to date on poly(vinyl esters) refer to industrial products; they are therefore only valid for the composition used in each case.

There are no indications that the poly(vinyl esters) investigated are toxic by oral administration; poly(vinyl acetate) see [61]. Poly(vinylesters) from C_2–C_{18} unbranched fatty acids are therefore permitted together with the comonomers listed individually in the corresponding regulations [55–57] and the accompanying substances for coating cheese and as additives for the production of chewing gum.

Economic Aspects. For the production of polymers based on vinyl esters there are no reliable statistical figures. The production capacity for vinyl acetate in 1990 (in 10^3 t/a) gives an indication of the order of magnitude [62], [63]:

	1991	1994
Western Europe	590	655
Germany	290	–
Eastern Europe	300	116
Former Soviet Union	115	–
North and South America	1480	1775
United States	1280	1500
Asia	930	953
Japan	570	–

The consumption of vinyl acetate is assumed to be ca. 800 000 t in the United States, ca. 660 000 t in Western Europe, and 550 000 t in Japan in 1990. The distribution of the consumption of vinyl acetate among the different products varies in the individual regions. In Western Europe the following quantities of vinyl acetate are consumed in the most important areas of use:

Poly(vinyl acetate) emulsions	ca. 430 000 t
Poly(vinyl alcohol)	ca. 120 000 t
Poly(vinyl acetal) and other uses	ca. 110 000 t

Poly(Vinyl Ethers)

General aspects of polymers, properties and testing, processing, additives, and analysis are discussed in Plastics, General Survey; Plastics, Properties and Testing; Plastics, Processing; Plastics, Additives; and Plastics, Analysis, respectively. States of order are treated in Plastics, Properties and Testing. Fundamental aspects of polymerization reactions are treated in Polymerization Processes.

1. Introduction

Industrially important poly(vinyl ethers) are compounds with the general formula: -$(CH_2CHOR\text{-})_n$ where R is an alkyl group such as methyl, ethyl, isobutyl, or octadecyl.

Poly(vinyl ethers) were first prepared by WISLICENUS, who in 1878 produced a balsam-like product from 700 mols of vinyl ethyl ether [*109-92-2*] and 1 mol of iodine [1]. This reaction was recognized as a chain reaction involving a cationic polymerization initiated by I^+ and chain growth via carbonium ions.

In the 1920s the monomeric vinyl ethers [2] became readily available by Reppe vinylation of alcohols with acetylene and grew in industrial importance. Their polymerization was researched systematically.

After 1930 vinyl ethers and poly(vinyl ethers) were produced on an industrial scale, initially at the Ludwigshafen works of the I. G. Farbenindustrie (now BASF), and since 1940 at the General Aniline and Film Corporation (GAF) in the United States, and later also by Union Carbide (UCC) in the United States.

Today (1991) poly(vinyl ether) homopolymers are only produced by BASF; UCC and GAF have ceased production. Poly(vinyl ether) homopolymers are used as raw materials for adhesives.

Copolymers of vinyl ethers with other monomers, such as maleic anhydride, vinyl chloride, or acrylic esters, are produced by GAF and BASF. They are used as auxiliary materials for adhesives and paints, and in many other industries. General information on poly(vinyl ethers) can be found in [3–5].

2. Production

Monomers. Poly(vinyl ethers) are produced exclusively by polymerization of vinyl ether monomers.

In addition to the vinylation of alcohols with acetylene, the vinylation of alcohols with ethylene also leads to alkyl vinyl ethers, according to patents of Union Oil of California [6]. However the process has not become established industrially.

The very reactive α-methylvinyl ethers [7]

are only of academic interest.

With both strong and weak initiators and independent of the polarity of the solvent used, they give polymers with syndiotactic structures [8].

The stereochemistry of the polymers from β-methylvinyl ethers

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a22_011

has been intensively investigated [9–15]. Polymers of vinyl ethers which are substituted at the alkyl group by, for example, chlorine [16], oxyethylene groups [17], a phthalimide group [18], an acetoxy group [19], a 9-carbazolyl group [20], a trifluoroalkyl group [21], or an acrylate or sorbate group [22], also have no industrial importance.

Of the industrially important vinyl ethers (methyl [*107-25-5*], ethyl [*109-92-2*], isobutyl [*109-53-5*], and octadecyl [*930-02-9*]), vinyl methyl ether has the greatest economic growth rate.

Initiators. *Anionic initiators* are unsuitable for the polymerization of vinyl ethers.

With *radical initiators* such as azoisobutyronitrile [23], peroxides [24], or redox systems [25], vinyl ethers polymerize to give homopolymers with a low reaction rate and a low degree of polymerization. However, copolymers from vinyl alkyl ethers and maleic anhydride in a molar ratio of 1 : 1 can be produced at a high rate with radical initiation, the polymer chains being constructed from both monomer units in a strictly alternating sequence.

Copolymers of vinyl ethers and vinyl chloride or vinyl ethers and acrylic esters contain a maximum of 50 mol % vinyl ether.

Cationic initiators are very suitable for the polymerization of vinyl ethers. They require high-purity monomers and solvents and clean apparatus; the absence of water is particularly important.

Friedel–Crafts catalysts , such as BF_3, $AlCl_3$, $SnCl_4$, or their complexes (e.g., BF_3 dietherate or BF_3 dihydrate), and also acidic aluminum sulfate, are widely used [26].

Other initiators such as halogens [27], protic acids [28], halogenated metal alkyls [29], cation-forming salts (e.g., $Ph_3C^+BF_4^-$) [30], Ziegler–Natta catalysts [31], and high-energy radiation [32], [33] are of theoretical interest.

Stereoregularity. Poly(vinyl ethers) were the first group of compounds in which the phenomenon of stereoregularity was recognized [34], [35]. Depending on the choice of polymerization conditions, either an amorphous or a crystalline polymer, which were later recognized as atactic or isotactic, can be produced from vinyl isobutyl ether [36]. For further details see [4].

Living Polymers. In 1984 it was discovered that in nonpolar solvents the initiator system $HI-I_2$ can convert vinyl isobutyl ether to living polymers [37]. The number-average molecular mass of the poly(vinyl isobutyl ether) increases with increasing monomer conversion, but is inversely proportional to the initial concentration of initiator. The molecular mass distribution is very narrow: the quotient of the weight-average and number-average molecular masses is close to 1, whereas for conventional poly(vinyl ethers) it is ca. 3. This interesting process is, however, not used commercially.

3. Industrial Processes

3.1. Batch Bulk Polymerization of Vinyl Methyl Ether

In one process 200 mL of an initiator solution (3 % boron trifluoride dihydrate in dioxane) is charged to a stirred-tank reactor containing 300 L vinyl methyl ether (*bp* 6 °C) at 12 °C. The reactor is cooled by jacket cooling and is equipped with a reflux condenser.

After the strongly exothermic polymerization is initiated, 5300 L vinyl methyl ether (in 10 h) and 6 L initiator solution (in 16 h) are continuously pumped into the stirred reactor against a regulated internal pressure of ca. 0.3 bar. The reactor temperature is ca. 15 °C. The heat of reaction (1400 kJ/kg monomer) is removed via the reactor jacket and the reflux condenser. Three hours after addition of the monomer is complete the temperature is increased to 60 °C, and 2 h later to 90 °C. After a further 2 h the reflux condenser is removed and the automatic cooling switched off. Two hours later the stirrer is switched off.

After a further 2 hours the reactor is degassed for 4 hours. The contents of the reactor are then either emptied out directly as a hot polymer melt or transferred to a mixer where they are converted into 50–70 % solutions with solvents such as water, ethanol, or toluene.

About 97 % of the monomeric vinyl methyl ether is converted to a light yellow soft resin, with $\bar{M}_w \approx 60\,000$ and $\bar{M}_n \approx 20\,000$ (commercial name Lutonal M 40). Polymers from vinyl ethyl ether (*bp* 36 °C) and vinyl isobutyl ether (*bp* 83 °C) can be produced analogously.

3.2. Continuous Bulk Polymerization of Vinyl Ethyl Ether

4600 mol/h (440 L/h) of vinyl ethyl ether and 0.4 mol/h of an initiator in solution are continuously pumped into a 2.5 m^3 stirred reactor. The reaction temperature is 98 °C, and the heat of reaction (ca. 1100 kJ/kg) is removed by jacket cooling and a reflux condenser.

The liquid level in the stirred reactor is kept constant by a siphon overflow. The polymer running out is collected in a larger receiver in which unreacted monomer is polymerized. The product is homogenized and then removed in batches as a viscous liquid. The molecular mass $\bar{M}_w$ is 3300 and $\bar{M}_n$, 1400 (commercial name Lutonal A 25). A viscous polymer with $\bar{M}_w = 17\,000$ can be produced analogously from vinyl isobutyl ether (commercial name Lutonal I 30).

3.3. Continuous Solution Polymerization of Vinyl Isobutyl Ether

The low-temperature polymerization of vinyl isobutyl ether in liquid propane on a conveyor belt [26] is no longer used due to poor economics.

3.4. Environmental Protection

The off-gases formed in the production of poly(vinyl ethers) are contaminated by solvent and monomer vapors; they are collected and incinerated. The off-gases from incineration are discharged to the atmosphere. In the market, solvent- containing poly(vinyl ether) products are declining in importance, while 100 % polymers and aqueous systems are exhibiting growth – a favorable tendency for environmental protection.

4. Properties and Uses

Consistency and Compatibility. Commercial poly(vinyl ethers) are highly viscous oils, soft adhesive resins, or nonadhesive elastomers, depending on the molecular mass. Poly(vinyl octadecyl ether) has a waxlike consistency.

Poly(vinyl ethers) are resistant to saponification by dilute acids and bases. Their solubility in water and organic solvents and their compatibility with other polymers depends on the nature of the alkyl group. For example, poly(vinyl methyl ether) (Lutonal M 40) is soluble in aromatic hydrocarbons, insoluble in aliphatic hydrocarbons, and soluble in alcohols and cold water. Formation of hydrogen bonds between the ether oxygen and water is responsible for the solubility in cold water. These bonds are destroyed on heating, and above 28 °C the polymer precipitates from aqueous solution.

Poly(vinyl methyl ether) forms clear films when mixed with many other polymers such as methyl cellulose, ethyl cellulose, nitrocellulose, epoxy resins, natural rubber, poly(vinyl acetate), vinyl acetate – vinyl chloride copolymers, and polystyrene. It can also be used as a plasticizer.

Poly(vinyl ethyl ether), a highly viscous oil, soft resin,or nonadhesive material,depending on the molecular mass, is soluble in ethers, esters, ketones, and hydrocarbons, but insoluble in water.

Poly(vinyl isobutyl ether) is produced as a highly viscous oil and as a soft resin, but also as a secondary emulsion in water for mixing with other aqueous polymer emulsions.

Poly(vinyl octadecyl ether) is a brittle solid which melts at 50 °C and is compatible with many waxes.

Uses. Uses of some commercial poly(vinyl ethers) are listed in Table 1.

The economically most important use of poly (vinyl ethers) is in the adhesives industry, mostly as modifying additives for other (cheaper) raw materials. Depending on the nature of the poly-(vinyl ether), adhesives for labels, for flexible tapes, or adhesives which stick well to polyethylene, on a moist background, or at low temperatures can be produced. For further information on the uses of poly(vinyl ethers) see [5], [38].

Table 1. Uses of poly(vinyl ethers)

Poly(vinyl ether)	Trade name	Consistency	Use
Methyl	Lutonal M 40	soft resin	raw material for adhesives
	ca. 50 % in water	highly viscous solution	plasticizer thickener heat sensitizer
	70 % in ethanol	highly viscous solution	raw material for adhesives
	70 % in toluene	highly viscous solution	raw material for paints
Ethyl	Lutonal A 25	highly viscous oil	raw material for paints auxiliary for printing inks
	Lutonal A 50	soft resin	raw material for adhesives
	70 % in naphtha	highly viscous solution	plasticizer
	70 % in ethanol	highly viscous solution	plasticizer
	70 % in toluene	highly viscous solution	plasticizer
	Lutonal A 100, ca. 25 % in hexane	highly viscous solution	raw material for adhesives
Isobutyl	Lutonal I 30	highly viscous oil	raw material for adhesives
	Lutonal I 60	soft resin	raw material for adhesives
	50 % in heavy naphtha	highly viscous solution	raw material for paints
	80 % in light naphtha	highly viscous solution	raw material for adhesives
	Lutonal I 60 D	medium-viscosity aqueous dispersion	raw material for adhesives
	Lutonal I 65 D	medium-viscosity aqueous dispersion	raw material for adhesives
Octadecyl	Luwax V	wax	polish for floors and other surfaces

5. Copolymers

Vinyl ethers readily undergo cationic copolymerization with one another, but the resulting copolymers are unimportant industrially. Radically produced copolymers from vinyl ethers and other monomers contain a maximum of 50 mol % vinyl ether. Solutions (e.g., in ethyl acetate) or aqueous emulsions of radical copolymers containing up to 30 % vinyl isobutyl ether are used as raw materials for adhesives with special adhesive and compatibility properties. Copolymers with 75 % vinyl chloride and 25 % vinyl isobutyl ether are used as binding agents for ageing-resistant, flexible anticorrosion paints.

Copolymers of vinyl methyl ether and maleic anhydride are very versatile in their applications, being used as protective colloids, thickeners, pigment dispersants, film formers, and binding agents. Products of this type are produced by GAF (trade name Gantrez) and BASF (trade names Sokalan, Luviform, Lupasol) for use as detergent additives, in the paper and textile industries, in cosmetics, and in the production of microcapsules. For further information see [5]. GAF sells the copolymer as a white powder, which, on dissolving in water, forms a maleic acid – vinyl methyl ether copolymer and, on dissolving in an alcohol, a maleic acid half ester – vinyl methyl ether copolymer.

6. Toxicology

For the common poly(vinyl alkyl ethers) known for nearly 50 years (methyl, ethyl, isobutyl, and octadecyl), no effects which are hazardous to health have so far been found. In animal experiments they are classified as nonirritant to the skin and nonmutagenic. The oral toxicity LD_{50} (rat) is > 500 mg/kg.

The toxicity of organic poly(vinyl ether) solutions is determined essentially by the solvent. Toluene and *n*-hexane present in naphtha have a narcotic effect, irritate the eyes and skin, and can produce permanent damage to the nervous system. Good workplace ventilation is necessary.

1. Introduction

Vinylidene chloride (1,1-dichloroethylene), VDC, was first obtained by V. REGNAULT in 1838 by treating 1,1,2-trichlorethane with alcoholic caustic potash solution to produce a colorless, chemically impure liquid having a boiling point of 35–40 °C which was subsequently recognized as being impure VDC [2]. The processes used today are still based on this reaction (see → Chlorinated Hydrocarbons, Chap. 3.2.).

When vinylidene chloride is stored and particularly when exposed to light (E. BAUMANN, 1872), a white precipitate is formed.

This precipitate was identified by FEISST and STAUDINGER (1930), who carried out the first systematic polymerization experiments [3], [4], as poly(vinylidene chloride) homopolymer. It was found that poly(vinylidene chloride) (PVDC) could not be processed thermoplastically because of its thermal instability. R. M. WILEY [5] succeeded in obtaining processable materials by copolymerization and plasticization. Because of the special properties of PVDC, this polymer was intensively researched and further developed in the 1930s (in the United States by Dow in particular, and in Europe by BASF). For further information on the historical development, see [6–12].

The first poly(vinylidene chlorides) were marketed more than 50 years ago. They were originally used mainly for resistant fibers and bristles. Coatings of PVDC were first applied in significant quantities around 1940 in the United States and in Germany. The first extruded shrink PVDC films for meat packaging also appeared at that time.

However, large-scale development of this class of products did not start until the 1950s when improved PVDC resins for coatings came onto the market; early examples of this class of high-grade polymers were the soluble Saran resins (F and B) and Saran dispersions of Dow and the Diofan dispersions of BASF.

All conventional commercial PVDC products are now copolymers of vinylidene chloride with small amounts of other monomers. The VDC content of these polymers is usually between 75 and 95 %, and in special cases is as low as 50 % (e.g., VDC – VCM copolymers).

2. Production

Due to its asymmetric structure, VDC polymerizes readily at its double bonds; comonomers are used for modification. The main comonomers are methyl acrylate, ethyl acrylate, acrylonitrile, methyl methacrylate, butyl acrylate, and vinyl chloride.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a22_017

Small amounts of unsaturated carboxylic acids or other products with adhesion-promoting groups are also used to obtain improved anchorage or other special coating properties.

Two processes are used to produce PVDC copolymers on an industrial scale, which are of comparable commercial importance: emulsion polymerization and suspension polymerization, also known as bead polymerization.

Vinylidene chloride polymerizes in the presence of ionic and radical initiators and Ziegler catalysts and under the influence of radiation. Ionic polymerization has the disadvantage that initiators such as butylithium react with the polymer and accelerate its degradation. Up to now, only radical polymerization in aqueous systems has been of industrial interest.

Comparison of the Processes. On the commercial scale, the heterogeneous polymerization of VDC is carried out by the suspension and emulsion processes in presence of radical sources.

Radiochemical and anionic initiation suffer from the impossibility of excluding polymer degradation, and cationic polymerization gives low molecular mass polymers. Ziegler polymerization of VDC has never been developed.

Homogeneous solution polymerization has not been described in patents. Bulk polymerization and precipitation polymerization in inert solvents such as cyclohexane or benzene cannot be controlled in practice owing to the associated engineering problems such as stirring and heat removal. In bulk polymerization, the reaction mixture thickens to a paste at 10 – 20 % conversion. In the presence of inert solvents the reaction is too slow, only low molecular masses are attained, and the polymer must be freed of solvent.

Suspension polymerization in water can be well controlled but, especially in the case of VDC – VC copolymers, requires quite long reaction times to reach the high molecular masses attained in emulsion polymerization. Owing to their low concentration of polymerization additives, suspension polymers are generally more stable and less sensitive to water.

The composition of the copolymer can be better controlled in emulsion polymerization by the metering in of monomer.

Suspension and emulsion polymerization are carried out in stirred, glass-lined or stainless steel autoclaves. Heat is supplied or removed by jacket heating or cooling. The reactors are flushed free of oxygen before polymerization. The water added must be free of metallic impurities, or the thermal stability of the polymers is impaired.

Purity and Storage of the Monomers. The VDC monomer used for polymerization contains 200 ppm *p*-methoxyphenol or 0.6 – 0.8 % phenol as stabilizer. Polymerization is practically unaffected by *p*-methoxyphenol, while phenol must be removed before polymerization by distillation or alkaline extraction.

Vinylidene chloride is stored under a nitrogen protective atmosphere in nickel-plated or phenol- coated vessels. The oxygen content in the stock tank must not exceed 100 ppm.

On storage VDC can form peroxides, especially with nonstabilized VDC and oxygen. These peroxides can lead to spontaneous polymerization, but are also explosive in the presence of air or oxygen, even at low temperatures (– 40 °C). The peroxides can be detected by their pungent, acrid smell or by the formation of flocculent deposits of polymer. They are deactivated on storage under water, and can be destroyed by washing with a 5 % solution of methanol in tetrachloroethylene. PVDC peroxide decomposes into phosgene and formaldehyde [13].

2.1. Emulsion Polymerization

VDC is polymerized by batch [14] or monomer-addition [15–19] processes. The mechanism of the polymerization cannot be described by the Smith – Ewart theory [20]. Typical polymerization recipes in parts by weight are as follows:

Batch process

Vinylidene chloride	78
Vinyl chloride	22
Water	180
Potassium peroxosulfate	0.22
Sodium metabisulfite	0.3
Sodium dioctylsulfosuccinate (80 %)	3.58

Monomer-addition process

Vinylidene chloride	468
Comonomer	52
Dihexylsulfosuccinate	15
Sodium lauryl sulfate (5 %)	5
Ammonium peroxosulfate (5 %)	10
Sodium metabisulfite	10
Water	440

In batch polymerization at 30 °C, 95 – 98 % conversion is reached after 7 – 8 h [15]. Polymerization to completion of batch charges gives copolymers with broad comonomer distributions [21], except when the copolymerization parameters r_1 and r_2 equal 1.

Figure 1 shows a flow sheet of the monomer-addition process.

The monomers are charged to a mixing tank, and aqueous solutions of the emulsifiers and the initiator and of the redox activator are prepared. After the reactor has been closed and heated to 40 °C, one-tenth of the monomer mixture and one-tenth of the aqueous initiator and redox activator solutions are run in via computer-controlled metering pumps. After the reaction has started, the three streams are added at preprogrammed rates. The reactor internal temperature is kept constant by means of the jacket temperature, and the reactor pressure approximately constant by addition of the activator. After completion of the main reaction, further initiator and activator are added to allow the system to react to completion. The residual monomers are withdrawn at elevated temperature under vacuum, or unreacted VDC is stripped out by treating the dispersion with steam or hot inert gases. The resulting latex has a solids content of 52 % and can be transported as such or coagulated to give a resin. The wall deposits formed during polymerization are removed between batches, e.g., by spraying with high-pressure water.

In VDC emulsion (co)polymerization, anionic emulsifiers such as sodium alkylarylsulfonates, alkyl esters of sodium sulfosuccinic acid, and fatty alcohol sulfates are used alone or in combination with nonionic surfactants such as ethoxy-lated alkylphenols. The usual initiators are peroxosulfates, hydrogen peroxide, organic hydroperoxides, peroxoborates, and peroxocarbonates in the presences of redox activators such as bisulfites or formaldehyde sodium bisulfite. Redox systems are used to obtain high molecular mass products at low temperatures and acceptable space – time yields.

Polymerization is preferably carried out at pH 2 – 4 to avoid attack by bases, and the operating temperature must be below 80 °C to suppress polymer degradation. Feed tanks, polymerization reactors, and monomer removal units are often made of glass-lined steel to avoid metallic impurities.

Because the reaction is carried out under controlled conditions, copolymers manufactured by the continuous addition process have uniform comonomer distribution [15–19]. The copolymers are present in the latex state in the amorphous form and can be used directly as coating materials with good film-forming properties.

The principal VDC copolymers produced by emulsion polymerization are those with acrylonitrile and/or various (meth)acrylates [22–27], while VDC – vinyl chloride copolymers are produced in smaller volume [14], [28], [29]. The copolymers are used as dispersions of 50 – 60 % solids content, or first coagulated, washed, and dried, and then processed as solution. For coagulation, the dispersion is diluted to 30 % solids content to lower its viscosity, and aluminum or calcium salts are added. The polymer is then filtered, washed, and dried.

2.2. Suspension Polymerization [11], [12]

A typical charge for the suspension polymerization of VDC (in parts by weight) is as follows

Vinylidene chloride	80
Vinyl chloride (VC)	20
Water	200
Methyl hydroxypropyl cellulose	0.2
Dilauroyl peroxide	0.6

Figure 2 shows a flow sheet of the process. In 30 – 60 h at a polymerization temperature of 60 °C a conversion of 85 – 90 % is achieved.

Residual monomers can be removed by steam treatment in downstream stripping columns or in the polymerization reactor itself by vacuum degassing or steam treatment at reduced pressure. Residual monomers are recycled. The reactors are cleaned with high-pressure water after each batch.

The monomer-free suspension enters intermediate tanks of rustproof material in which sev-

Figure 1. Flow sheet for the production of VDC copolymers by monomer-addition emulsion polymerization

Figure 2. Flow sheet for the production of VDC – VC copolymers by suspension polymerization

eral batches can be homogenized. The tanks also provide a buffer for the continuous processing of the product.

After centrifuging off and washing with water, the product is dried at ca. 50 – 70 °C in cocurrent flow in a drum dryer, sieved, and then conveyed pneumatically to storage bins.

Whereas polymerization was formerly carried out only in glass-lined reactors, since ca. 1970 stainless steel reactors have also been used.

In suspension polymerization organic peroxides, peroxocarbonates, and azo compounds are used as initiators, and poly(vinyl alcohols) and methyl celluloses as suspension agents. Before polymerization, the initiator must be distributed uniformly in the monomer mixture to avoid different rates of polymerization in the dispersed monomer droplets. Droplets that polymerize rapidly are converted to hard, glassy suspended particles which are difficult to process. The polymerization rate increases with increasing initiator concentration and temperature. The suspension agents influence the particle size distribution, porosity of the particles, and clarity and transparency of the processed products. Secondary suspension agents such as sorbitan monostearate improve the porosity and plasticizer absorption of the polymer powder.

Reproducible setting of adefined comonomer distribution in the polymer is more difficult in suspension polymerization than in emulsion polymerization. Unmodified batch operation [30], as well as temperature-programmed polymerization and the use of initiators with different decomposition rates [31], lead to a polymer mixture with heterogeneous polymer composition. In VDC – VC copolymerization, uniform monomer incorporation is achieved by contin-

uously removing the less reactive monomer to maintain a constant volume ratio in the unreacted monomer mixture [32]. The polymerization rate can be increased by stepwise polymerization with more active initiators such as peroxodicarbonates [33].

Suspension polymerization is mainly used to produce VDC – VC copolymers [31], [34], which are suitable for injection molding and extrusion molding. Modified VDC – alkyl acrylate [35] and VDC – methyl acrylate copolymers [36] can be processed by blow molding.

3. Structure and Properties [10–12]

3.1. Homopolymers

PVDC does not dissolve in monomeric vinylidene chloride, and polymer and monomer are practically insoluble in water. Vinylidene chloride polymerizes in the presence of radical sources to give a linear, symmetrical macromolecule with head-to-tail structure and the repeat unit

The theoretical chlorine content of the polymer is 73.14 %, although in practice chlorine contents of 72 – 73 % are obtained.

The polymer chain is tightly packed in the solid state, and in the thermodynamically stable state it is highly crystalline (ca. 75 %), indicating the absence of defects or branches. The crystallinity and rate of crystallization are influenced by the polymerization conditions, the mechanical and thermal treatment of the polymer, and, in the case of copolymers, the comonomer content.

The combination of high crystallinity and high density results in PVDC having very good barrier properties against gases and vapors and resistance to solvents.

The absolute molecular mass of PVDC cannot be determined by conventional methods due to the lack of a suitable solvent. Like other high-melting polymers, PVDC is sparingly soluble. Only at temperatures of 130 °C can 1 % solutions be prepared in, e.g., 1,3-dibromopropane or bromobenzene. At room temperature PVDC dissolves only in polar solvents such as hexamethylphosphoric triamide or tetramethylene sulfoxide; amorphous PVDC dissolves in tetrahydrofuran.

The structure and solubility of PVDC are independent of the polymerization temperature.

PVDC decomposes at temperatures above 125 °C, chiefly with elimination of hydrogen chloride and formation of polyene sequences. The degraded polymer is infusible, and the crystalline structure is destroyed [37]. The polymer is also degraded by the action of high-energy radiation, bases, and heavy metal ions.

Some properties of PVDC are as follows:

Melting point	198 – 205 °C
Glass transition temperature	− 19 to − 11 °C
Amorphous density (25 °C)	1.67 – 1.775 g/cm^3
Crystalline density (25 °C)	1.80 – 1.97 g/cm^3
Degree of polymerization	100 – 10 000
M_w/M_n	1.5 – 2.0
Softening range	100 – 150 °C
Ceiling temperature	350 – 400 °C

3.2. Copolymers

Industrially important copolymers are those manufactured by radical polymerization of VDC with vinyl chloride, acrylonitrile, and (meth)-acrylate esters. Table 1 lists the copolymerization parameters of VDC with the most important comonomers [10]. The Q and e values of VDC are $Q = 0.20$ and $e = 0.36$ [38].

Table 1. Copolymerization parameters of vinylidene chloride with various comonomers

Comonomer	r_1	r_2	Temperature, °C
Styrene	0.14	2.0	60
Vinyl chloride	3.2	0.3	60
Acrylonitrile	0.37	0.91	60
Methyl acrylate	1.0	1.0	60 – 70
Methyl methacrylate	0.24	2.53	60
Vinyl acetate	6	0.1	68

Copolymers with high VDC content have lower melting points and, at least at low comonomer content, higher glass transition temperatures than the PVDC homopolymer. Figures 3 and 4 show the effect of the copolymer composition on the melting point and glass transition temperature.

Figure 3. Dependence of melting point on copolymer composition
a) VDC – vinyl chloride; b) VDC – methyl acrylate; c) VDC – octyl acrylate

Figure 4. Dependence of glass transition temperature on copolymer composition
a) VDC – acrylonitrile; b) VDC – methyl acrylate;c) VDC – ethyl acrylate

VDC copolymers are more stable to degradation than pure PVDC. Comonomers interrupt the unstable poly(vinylidene chloride) chain. The copolymerization must therefore be conducted so that as few long PVDC sequences as possible are present in the copolymer. Furthermore, VDC – VC copolymers are more stable than PVDC since the chlorine – carbon bond is stronger in the vinyl chloride unit than in the VDC unit. Polar functional groups, however, weaken the chlorine – carbon bond, so that copolymers with polar functional groups such as the nitrile group are less stable due to neighboring group effects.

The mechanical properties of VDC copolymers depend on temperature, molecular mass, crystallinity, degree of orientation, and plasticizer content. With increasing crystallinity the strength increases, whereas toughness and elongation decrease. The above properties are improved by orientation.

Incorporation of vinyl chloride, for example, in the VDC polymer chain raises the glass transition temperature, which leads to less favorable low-temperature behavior (increased brittleness). The glass transition temperature can be lowered again without loss of strength properties by plasticization (2 – 10 % plasticizer).

Crystallinity. The performance of PVDC films and coatings is greatly influenced by the high chlorine content of the polymers and especially their crystallinity.

The polymer molecule is very symmetrical if the proportion of VDC in the polymer is high, which leads to crystallization. It has been shown that the crystallinity is directly proportional to the mole fraction of VDC in the polymer. Thus, homopolymers of VDC are highly crystalline, i.e., they contain between 50 and 80 % of crystalline material, the actual figure depending on the polymerization conditions. For this reason, they are normally unsuitable for further processing.

The symmetry of VDC polymer chains is disturbed by the incorporation of comonomers such as methyl acrylate. The crystallinity decreases steadily with decreasing mole fraction of VDC until it is completely suppressed at ca. 80 mol % VDC.

If the mole fraction of VDC in the copolymer is very high (93 % VDC), the polymer particles of a PVDC dispersion may already crystallize in the aqueous phase. It is very difficult for such highly crystalline latex particles to fuse together, with the result that film formation on drying is hardly possible. For this reason, the VDC mole fraction in PVDC dispersions for general applications usually lies between 87 and 92 mol %.

The partially crystalline morphology of PVDC copolymers can best be described by a network of continuously interpenetrating crystalline and amorphous zones.

Studies on crystallization of coatings have revealed that if the mole fraction of VDC in the copolymer is ca. 88 %, the amorphous state is retained for a long time (200 – 300 d under normal conditions) and that the crystalline phase is formed very slowly.

If the coatings contain a high proportion of VDC (91 – 92 %), crystallization already commences after 1 d and attains a maximum within 5 – 20 d, depending on the product. This stage is referred to as primary crystallization. Further, secondary crystallization is slight and proceeds slowly.

Table 2. Demands imposed on the properties of PVDC in relation to the mole fraction of VDC in the copolymers and the crystallinity

* + = improvement, — = deterioration.

Table 2 reviews the effect of increasing the VDC content in copolymers and the crystallinity on the properties of coatings and the processability of PVDC.

Permeability [39]. It has been found that the most water vapor-resistant polymers are the most oxygen permeable and vice versa, with the exception of PVDC, which acts as a very good barrier to both (see → Films, Chap. 2. for comparison of permeability data). Table 3 lists the permeability of three PVDC grades.

Aromaproofness is closely related to the impermeability to water vapor or gases. It is important in practice that the contents of a pack should not lose their aroma as a result of diffusion from the inside to the outside. Likewise, their aroma must not be impaired by the diffusion of odoriferous substances from the outside to the inside.

The very good aromaproofness derives from its high resistance to diffusion and low solubility, particularly that of the crystalline sections of the polymers.

Figure 5. Aroma barrier properties of 25 µm plastic films

	40 – 80	135 – 265	15 – 25

* Permeability in cm^3 µm m^{-2} d^{-1} bar^{-1} (dry gas).
** Permeability in g µm m^{-2} d^{-1}.

Figure 5 illustrates the good aroma barrier of PVDC- coated BOPP (biaxially oriented polypropylene) films (26 µm) in comparison with coextruded OPP and OPP coated on both sides with acrylic for limonene and menthol.

Resistance to Oils, Fats, and Chemicals. Pinhole-free films or coatings of PVDC offer high resistance to animal and vegetable fats and oils. It is not swollen by oil or grease, nor does it permit their diffusion. Exceptions are strongly unsaturated vegetable oils, which may cause amorphous grades of PVDC to swell somewhat.

Poly(vinylidene chloride) exhibits excellent chemical resistance. The crystallinity, the large volume proportion of chlorine, as well as the high density are responsible for the high resistance to numerous solvents and chemicals.

4. Processing and Uses

4.1. Extrusion

The commercial extrusion grades of PVDC are copolymers of vinylidene chloride with comonomers such as vinyl chloride, acrylic or methacrylic acid esters, and others. They are polymerized in emulsion and coagulated, or directly polymerized in suspension; they are generally available in powder form.

Normal processing formulations of those copolymers require a plasticizer and/or a stabilizer; some include, if necessary, a lubricant for the extrusion process, a slip agent if requested by the final properties of the extrudate, pigments, light stabilizers, and impact modifiers.

A typical PVDC film formulation, for instance, contains 0 – 10 % plasticizer (e.g., dibutyl sebacate, acetyltributylcitrate), 0.5 – 5 % stabilizer (e.g., epoxidized soybean oil, sodium pyrophosphate), 0 – 1 % lubricant (e.g., fatty acids and fatty acid amines, montan wax). The dry blend (formulated PVDC) is extruded in single-screw extruders at a compression ratio from 1/3.5 to 1/4.5. A ratio of screw length to screw diameter of 10 – 24 has proven to be satisfactory.

Since PVDC, even stabilized, does not tolerate long periods at high temperature, which causes the release of hydrogen chloride and leads to carbonisation, all metal parts of the extruder and dies in contact with hot molten polymer must be made of corrosion-resistant, noncatalytic metals. Recommended materials are chromium (particularly for the screw) and nickel alloys.

4.2. Films and Sheets

One of the major outputs for PVDC resins is the manufacture of films.

It is possible to process PVDC as monolayer film or as part of a coextruded sandwich, both techniques allowing the preparation of shrink or nonshrink materials.

Shrinkage can be obtained by applying tension before cooling (orientation) or by crosslinking.

Monofilm Biorientation. Usual film process for monolayer PVDC film requires the extrusion of a molten tube; the temperature of the

PVDC melt is normally 150 – 160 °C, depending on the selected additives formulation.

The shrink film bubble process can be applied to both mono and coextruded film. Immediately after the die, the molten tube passes into a cooling bath (2 – 10 °C) which keeps the quenched cooled material in an amorphous state. The quenched, nontacky material is then slightly rewarmed in an oven and blown into a bubble. As the tube of amorphous polymer is oriented, crystallization takes place rapidly.

If a heat-stabilized film is desired, a further annealing step is applied by re-inflating the film and passing it through an infrared heating tunnel.

Figure 6. Cellulose film coating machine
a) Air preheater; b) Air heater; c) High-pressure chamber; d) Supply roll; e) Coating bath; f) Calibrating rolls; g) Smoothing roll; h) Rehumidifier; i) Receiving roll

Coextruded Film. Since PVDC monofilm does not meet all requirements of film packaging, although formulations already allow great versatility, PVDC films are being increasingly coextruded with other materials. This technique is used to optimize the film properties by combining materials in such a way, so as to add their own advantageous properties, while minimizing their drawbacks. Furthermore, it provides better PVDC barrier properties. Since the PVDC is no longer a self-supporting material, it is possible to reduce the amount of liquid additives that adversely affect barrier properties but are necessary in monolayer extrusion to insure mechanical properties. Also, it allows lower thickness of the PVDC film to be used if required.

Two coextrusion techniques have reached a high level of development: multimanifold die coextrusion and feedblock coextrusion.

The common feature of both techniques is the ability to process the materials that will be used in the final complex, on different extruders, the difference being how the different melts are joined.

In *multimanifold coextrusion*, each molten material is brought into the die through its own flow and distribution channel.

In the *feedblock system* the materials are combined before they enter the die.

Limitations of the feedblock system are that relative viscosities and extrusion temperatures of the different melts must be similar.

Permeability data for extruded and coextruded PVDC films are summarized in Table 4.

Coextruded sheets are produced with feedblock systems in the same way as for coextruded films. The more common structures are PP – TIE – PVDC – TIE – PP or PE; PS – TIE – PVDC – TIE – PS or PE; and PVC – PVDC – PVC, where TIE denotes an adhesive (tie) layer.

4.3. Lacquering and Coating [40–43]

PVDC lacquer resins (powder form) are vinylidene chloride copolymers modified to give solvent solubility; vinylidene chloride homopolymer is almost insoluble in usual solvents. The usual comonomers are acrylonitrile, vinyl chloride, acrylates, and methacrylate esters.

Copolymers with very high vinylidene chloride contents (> 90 %) are generally only soluble in THF mixtures.

Resins containing between 80 and 90 % VDC are less crystalline and therefore are also soluble in methyl ethyl ketone (MEK) mixtures.

Materials with lower VDC content are soluble in common organic solvents at room temperature, such as esters, ketones, and cyclohexanone.

Coating of Regenerated Cellulose (Cellophane). A major field of application for PVDC lacquers with a high VDC content in the copolymer is the coating of cellulose film.

These tailor-made PVDC resins develop high crystallinity and are therefore soluble only in aggressive solvents such as mixtures of

Table 4. Permeability of various PVDC structures

PVDC grade	Structure	Permeability to water vapor, g m^{-2} d^{-1}	Permeability to oxygen, cm^3 m^{-2} d^{-1} bar^{-1}
Aqueous dispersions	CBK ∗ + 15 g/m^2 PVDC	2.8 – 3.6	11 – 15
	CBK ∗ + LDPE + 20 g/m^2 PVDC	2 – 2.2	3.5 – 6.5
	PETP (12 µm) + primer + 3 – 5 g/m^2 PVDC	6 – 10	10 – 15
	PA6 (30 µm) + primer + 5 – 6 g/m^2 PVDC	6 – 11	7 – 10
	PVC (200 µm) + primer + 40 g/m^2 PVDC	0.6 – 1.1	2.6 – 3.3
	Cellulose film (37 – 48 g/m^2) + primer + 3 g/m^2 PVDC per side	5 – 8	3 – 6
Lacquer resins	Cellulose film (28 – 50 g/m^2) + primer + 1.5 g/m^2 PVDC per side	6 – 15	4 – 10
	PETP (15 µm) + 1.5 g/m^2 PVDC per side	9 – 10	12 – 14
	BOPP (20 µm) + 3 – 5 g/m^2 PVDC	3 – 5	5 – 11
Extrusion grades	EVA (20 µm)/PVDC (10 µm)/EVA (20 µm) nonoriented films		
	unplasticized PDVC	1 – 8	5 – 22
	2 % plasticizer	3 – 10	10 – 40
	4 % plasticizer	10 – 28	40 – 140
	PVDC monolayer (30 – 70 µm), 6 – 9 % plasticizer, heat shrinkable	8 – 15	30 – 200
	PVDC monolayer (15 – 25 µm), 4 – 6 % plasticizer, slightly heat shrinkable	5 – 15	15 – 60

∗ CBK = calendered bleached kraft.

THF/toluene or MEK/toluene. These solvent mixtures (for instance, THF/toluene 70/30 to 55/45) generally allow 10 – 20 % PVDC lacquers to be prepared. The required solution temperature is ca. 50 °C; the MEK/toluene mixtures must be heated to 70 – 75 °C to ensure complete dissolution.

Coating of cellulose film with PVDC is carried out by dipping on machines equipped with a vertical drying oven (Fig. 6).

To avoid blocking or sticking to the jaws of sealing machines, and to obtain the required slip properties, the following additives must be incorporated in the lacquer:

1) An additive to reduce sticking to the jaws of the sealing machine, such as fatty acids (behenic or stearic acid, for instance)
2) A natural wax (candellila, carnauba, etc.) or a synthetic wax (ketone or fatty amide) to improve blocking resistance
3) A mineral charge that roughens the surface to improve slip properties (silica, bentonite, talc, etc.)

Stabilizers are also incorporated in the solution in some cases to lower the corrosivity of the PVDC solution to metal parts of the machine.

As long as its moisture content is low, cellulose film constitutes a good barrier against gases; PVDC is thus applied to lower the water vapor permeability.

Barrier properties of cellulose film PVDC coated materials depend on the following factors:

1) Cellulose film composition
2) PVDC composition
3) PVDC coating thickness
4) Additives in the coating formula
5) Degree of crystallinity of the coating

Permeability data are listed in Table 4.

Lacquering of Paper, Foil, and Plastic Films. Some copolymers of vinylidene chloride are tailor polymerized to obtain good solubility at room temperature in a wide range of common organic solvents such as ketones and esters.

The interest of this family of product is:

1) Easier solubility
2) Heat sealability
3) Transparency and brilliance
4) Adhesion to a wide range of substrates
5) Good barrier properties and chemical resistance

These products, although less impermeable than the PVDC for cellulose film, are used for coating paper, plastic films, foils, and cardboards to lower their permeability (see Table 4) and make them heat sealable. They are also used as protective coatings. Coatings can be made by:

1) Coating on roll machines (reverse roll coating, squeeze coating, kiss coating, gravure roll coating, etc.)

2) Dip coating
3) Spray coating
4) Use of manual rollers or brushes

Depending on the final use, plasticizers, waxes, fillers, pigments, and dyes may be added to the solution.

Vinylidene chloride copolymers for coating are aqueous dispersions of copolymers with a high content of vinylidene chloride, in the form of a milky white liquid of low viscosity.

The usual comonomers are acrylic esters, unsaturated carboxylic acids, and vinyl chloride.

The PVDC aqueous dispersions are produced by emulsion polymerization. The dry solid content is 40 – 60 %.

They can be applied to papers and boards; plastics, films, and sheets; and aluminum. The nature and quantity of the comonomer is adjusted according to the substrate leading to the following coating grades of PVDC:

1) Grades for the production of nonblocking, sealable top coatings for paper, board, or paper-based laminates (paper – PE, paper – aluminum, etc.); these substrates may be pretreated, if necessary, with a grade of PVDC giving more flexible coatings and/or with a primer.
2) Grades for the production of sealable or nonsealable, nonblocking top coatings for plastic films (OPETP, BOPP, PE, rigid PVC, PA6, OPA, etc.). The films are coated with a primer or a first layer of PVDC (flexible grade) before coating with the nonblocking top coat.
3) Grades giving coatings that are more flexible, but also slightly more blocking and more permeable, than those made from the above grades. They are used mainly to coat paper, board, and paper-based laminates (with primer if necessary), and occasionally heavy-gauge plastic films with a primer.
4) Grades giving special coatings that adhere directly to certain plastic films without a primer. Their principal application is as an undercoat for subsequent coatings of another PVDC or PE applied by extrusion coating.
5) Grades for special coating or impregnation applications.

Although PVDC dispersions are in most cases supplied ready for use, under certain circumstances the user may need to introduce one or more additives to the aqueous dispersions prior to processing to modify the properties of the coating (surface characteristics, opacity, pigmentation, etc.) or the behavior of the product when applied by a coating or impregnation machine (corrosiveness, foaming, adjustment of coating weight, etc.).

PVDC dispersions are applied in roll-to-roll operations (web coating) in widths usually not exceeding 2500 mm. Processing speed has increased considerably in the last few years to 100 – 400 m/min.

The barrier properties of PVDC coatings depend on

1) Nature of PVDC (comonomers)
2) Quality of the substrate (porosity)
3) Coating weight and number of layers
4) Flexibility of PVDC and the substrate
5) Drying conditions
6) Crystallinity

Permeability data are listed in Table 4.

4.4. Uses

Extrudable grades are used for:

1) Monofilaments for the production of military combat boots and insoles, draperies and curtains, and filter applications
2) Medical applications, e.g., colostomy bags are made of monolayer or multilayer structures (EVA – PVDC – EVA)
3) Food packaging:
   Cling films, which are very thin films, slightly adhesive, used for wrapping foodstuffs, are monolayer films
   Shrink multilayer films (EVA – PVDC – EVA) are used to transport and store fresh cuts of meat between the slaughterhouse and the point of sale
   Some synthetic sausage skins are made of monolayer PVDC
   Rigid sheets (PP – PVDC – PP) are stable towards sterilization process and give shelf-stable storage

Aqueous dispersions are used for:

1) Pharmaceutical packaging blister packs for drugs which are very sensitive to water are made of PVC coated with PVDC.

2) Plastic food packaging:
   Biscuits are often packed in PVDC-coated OPP. Delicate chips or peanuts are packed in PVDC-coated PET laminated with LDPE. Cellulose casing for sausages is often coated with PVDC.
3) PVDC coated paper is often used for biscuits, cereals, and dried food.
4) Technical applications:
   PVDC is generally used for its water-resistance, fireproof or binder properties in applications such as coating carpet backings, wood chip panels, and cork coating.

Soluble grades are generally used for coating cellophane, and in some cases for plastic films (e.g., PETP).

5. Economic Aspects

PVDC copolymers as they arise from the polymerization are marketed by the raw material manufacturer as dispersions or powders under various names.

The best known trade names and producers are:

Amsco-res, Unocal (aqueous dispersions)
Daran, W. R. Grace (aqueous dispersions)
Diofan, BASF (aqueous dispersions)
Ixan, Solvay (aqueous dispersions, extrusion grades, lacquer resins)
Saran, Dow Chemical (extrusion grades, lacquer resins, PVDC films)
Serfene, Morton (aqueous dispersions)
Viclan, ICI (aqueous dispersions, lacquer resins, PVDC films)
Kureha (aqueous dispersions, PVDC films)
Asahi (aqueous dispersions, lacquer resins, PVDC films)

The PVDC world market (1990) is estimated at 125 000 t:

By countries:		By grades:	
Europe	26 %	Aqueous dispersions	32 %
Japan	38 %	Lacquer resins	6 %
United States	34 %	Extrusion grades	62 %
Others	2 %		

6. Toxicology and Occupational Health [44], [45]

Monomeric VDC is highly volatile. The vapor is denser than air and detectable by smell only at concentrations of 500 – 1000 ppm. When handling VDC the working area must be well ventilated. VDC vapors are highly inflammable and burn fiercely in air in the concentration range 7 – 16 vol %.

Animal tests and epidemiological investigations have not so far proved that VDC has a specific carcinogenic effect [46]. The mean VDC concentration in the workplace has been limited in the United States to 5 ppm (TLV) and in Germany to 2 ppm (MAK).

PVDC is mainly used for packaging foodstuffs or pharmaceutical products, involving both direct and indirect contact with the contents. Such packaging is governed by highly stringent regulations at an international level.

These regulations are generally based on positive lists with specific migration limits. PVDC satisfies all of these regulations.

Residual vinylidene chloride monomer in commercial polymers generally ranges from indetectable up to a few ppm since all modern producers have now adapted processes to outgas PVDC. These quantities are even lower when measured on coated or extruded materials.

In the United Kingdom, information on the content of VDC in food sold in retail outlets was collected by the MAFF [47]. Of the foods analysed, only snack foods and foods contained in VDC – VC copolymer-coated packs were found to contain measurable amounts of VDC. In most other cases of food packed in barrier-coated materials (polymer films and paper), the VDC content was below the detection limit of 0.03 – 0.05 ppm. From all the information available, the maximum possible intake of VDC per person, when averaged over the entire U.K. population, would be no more than 1 µg/d, in the worst-case assumption that all the residual VDC in food packaging was in fact ingested [47].

3.2. Potassium Hydride
3.3. Potassium Bases
3.3.1 Potassium Alkoxides
3.3.2 Potassium Amides
3.4. Potassium Superoxide
4. Acknowledgement

Potassium is the third element in the alkali metal group. This highly reactive metal is used to make potassium superoxide for use in self-contained breathing apparatus. Potassium in the form of alloys with sodium is used in industrial synthesis of alkylated aromatic hydrocarbons such as isobutylbenzene. Compounds of potassium derived from alcohols and amines are routinely used as bases in pharmaceutical and agricultural synthesis.

1. Potassium

HUMPHREY DAVY discovered potassium metal in 1807 upon electrolysis of molten potash (KOH) [1]. The English (and French) name for the element potassium is derived from the word “Potash”. The elemental symbol K (and the German name *Kalium*) comes from the Arabic *al kalzum*, meaning ashes.

Potassium [7440-09-7], atomic no. 19, is included in the group 1 elements comprising the alkali-metal family [2] and has the electron configuration $1s^2 2s^2 p^6 3s^2 p^6 4s^1$. All alkali metals carry a single, unpaired electron in the outermost electron shell. The alkali metals are the most electropositive elements known because of their great tendency to attain an inert gas structure by donation of the lone electron. This unique property renders all alkali metals strong reducing agents and good electron donors.

Potassium has three natural isotopes: ^{39}K (93.26 %), ^{40}K (0.012 %), and ^{41}K (6.73 %) [3]. The isotope ^{40}K, with a half-life of 1.25×10^9 years, is useful in determining geological age, disintegrating by electron capture to 89.33 ± 0.11 % ^{40}Ca and 10.67 ± 0.11 % ^{40}Ar. Several artificially produced isotopes of potassium are also known.

Potassium, the seventh most abundant element, does not occur in nature as a free metal. The abundance of potassium in the earth's crust is 2.59 %, mainly in silicates (feldspars, micas). The average content of potassium in seawater is 0.039 wt

% due to the weathering of minerals and varies depending on the distance from a river mouth [4].

Potassium minerals [5] are mined from salt deposits formed by crystallization and/or evaporation of marine regions during various stages of the earth's evolution. The most important potassium minerals are sylvite, sylvinite, carnallite, and langbeinite. Sylvinite is primarily potassium chloride (KCl, sylvite [6]) and sodium chloride (NaCl, halite) containing 20 – 30 % K calculated as potassium oxide (K_2O). The largest potassium chloride deposit is located in Saskatchewan (Canada). Langbeinite [7] is mainly potassium sulfate and magnesium sulfate with about 23 % K as K_2O. The largest deposit of carnallite, the double salt $KCl \cdot MgCl_2 \cdot 6\ H_2O$, is in Solikamsk (Russia). KCl can also be obtained by evaporation from the brines of Searles Lake in California, the Great Salt Lake in Utah, and the Dead Sea in the Middle East. Potassium nitrate is mined in Chile. Caustic potash (KOH), another important source of potassium, is primarily mined in Germany, New Mexico, California and Utah.

Potassium is indispensable for plants since it plays an important role in carbohydrate metabolism and the swelling of cells. Many plants accumulate 1 – 2 % potassium to grow at a normal rate. Therefore, KCl is widely used as a fertilizer to increase crop yields. In animal organisms, K^+ ions stimulate glycolysis, lipolysis, respiration of tissue, and the synthesis of proteins and acetylcholine. Potassium and sodium levels in higher animals are regulated by the kidneys.

1.1. Properties

Physical Properties. Potassium is a very soft, silvery metal with low density and melting point and very high thermal and electrical conductivities. The physical properties are summarized below [8].

Z	19
A_r	39.098
Crystal structure	body-centered cubic
Lattice parameter (17.3 °C)	0.531 nm
mp	63.25 °C
bp	759.9 °C
Atomic radius	277 pm
Ionic radius	151 pm
Ionization potential [9]	4.3407 V
Work function	2.24 eV
Standard reduction potential [10]	– 2.924 V
Electron emission threshold	0.65 μm
Electrical resistance	
0 °C	6.1 μΩ · cm
liquid, 63.2 °C	13.31 μΩ · cm
Density, 20.0 °C	0.856 g/cm^3
liquid, 63.2 °C	0.82 g/cm^3
300.0 °C	0.771 g/cm^3
Thermal conductivity	
21.0 °C	9.63×10^{-3} W m^{-1} K^{-1}
400.0 °C	4.00×10^{-3} W m^{-1} K^{-1}
Specific heat	
0.0 °C	0.737 J g^{-1} K^{-1}
50 – 100.0 °C	0.837 J g^{-1} K^{-1}
Heat capacity at 25 °C [11]	29.522 J g^{-1} K^{-1}
Latent heat of fusion	59.71 J g^{-1}
Latent heat of vaporization	2043 J g^{-1}
Hardness (Mohs scale)	0.5
Spectral lines	769.9, 766.5, 404.5 nm

Vapors of potassium metal remain diatomic (K_2) until the required dissociation energy of 49.6 ± 0.4 kJ (at 0 °C and 1.013 bar) is attained, causing the metal – metal bond to rupture: K_2 2 K. Potassium's vapor pressure is 164 mbar at 570 – 600 °C, and 521 mbar at 685 –700 °C. For the temperature dependence of the vapor pressure (vapor pressure equation), see [12]; for the vapor pressure curve, see [13].

Inelastic X-ray scattering methods were used to measure the high-frequency collective dynamics of molten potassium [14].

Chemical Properties. Potassium shares many common features with other members of the alkali metal group (Li, Na, Rb,

and Cs). Electropositivity increases from lithium to cesium. However, rubidium and cesium are too reactive for safe handling and they are not readily available on an industrial scale. Thus, potassium is the most electropositive and powerful industrial reducing agent from a practical and economical standpoint.

Although K, Na, and Li share certain attributes, each possesses unique chemical characteristics as well. Significant differences in ionic size and ionization energy lead to the distinctive chemical traits of each individual alkali metal. Potassium is the largest cation of the three, so organopotassium compounds are generally the most ionic. In polar solvents, potassium cations form loose ion pairs (or solvent-separated ion pairs) with their counteranions, whereas organolithium compounds tend to exist as aggregates (tetramers and hexamers), since lithium cations form tight ion pairs.

The smaller lithium cation is better suited to stabilizing localized (hard) carbanions, while the potassium cation stabilizes delocalized (softer) carbanions. Accordingly, the chemistry of sodium lies between those of potassium and lithium. Potassium's high reducing potential is demonstrated by the facile displacement of hydrogen atoms in weakly acidic hydrocarbons, amines, and alcohols (Table 1).

Table 1. Acidic compounds and their potassium derivatives

Compound	pK_a*	Potassium derivatives
1,3-Diaminopropane	35	$KNH(CH_2)_3NH_2$
Ammonia	35	KNH_2
Aniline	27	$KNHC_6H_5$
Acetylene	25	KC≡CH
tert-Butyl alcohol	18	$KOC(CH_3)_3$
Methanol	16	$KOCH_3$
Phenol	10	KOC_6H_5

*The expression pK_a refers to the pK_a of the conjugate acid from which the potassium base is formed.

The strong reducing potential of potassium metal is not limited to compounds containing active hydrogen. Potassium also reacts readily with various gaseous elements and inorganic substances (Table 2).

Table 2. Miscellaneous reactions of potassium

Element, compound	Conditions	Products
H_2	200 – 411 °C	KH
O_2	room temp.	KO_2
	200 – 300 °C	K_2O_2
X_2 (halogen)	room temp.	KX
S	70 °C	K_2S
H_2S	room temp.	K_2S
MX_n (metal salt)	various	M (metal)
C (graphite)	150 – 400 °C	C_8K
		$C_{24}K$, $C_{36}K$, etc.

Potassium forms three oxides: potassium monoxide, K_2O; the peroxide, K_2O_2; and the superoxide, KO_2. In dry air or dry oxygen, metallic potassium burns completely, forming potassium superoxide (KO_2). The propensity to form the superoxide resembles that of rubidium and cesium more than sodium. Under comparable oxidation conditions, sodium yields Na_2O_2, while lithium gives Li_2O.

Potassium does not react with saturated hydrocarbons, but potassium superoxide may explode in the presence of hydrocarbons [15]. Consequently, potassium is usually stored under inert gas because potassium can react with entrapped air in oils to form potassium superoxide. The metal has been used as a dispersion [16] in hydrocarbons, and is used in this form for chemical reactions. For many organic reactions, potassium is most easily handled as a liquid alloy with sodium.

Potassium metal is less dense than water and will float while reacting extremely rapidly with the water to form a colorless solution of potassium hydroxide (KOH) and hydrogen gas (H_2). The evolving hydrogen gas can explode violently. The

potassium metal melts due to the exothermic reaction then catches fire and burns with a characteristic pale lilac color. The resulting aqueous solution is caustic because of the dissolved potassium hydroxide.

Like other alkali metals, considerable amounts of potassium dissolve in liquid ammonia (ca. 480 g of potassium in 1000 g of ammonia at 0 °C). Depending on the concentration, potassium – ammonia solutions are blue to copper-colored, with electrical conductivities approaching those of liquid metals [17]. These special solvation characteristics have been the subject of comprehensive investigations [18]. Potassium dissolved in liquid ammonia reacts very slowly to form the amide (KNH_2). Transition-metal salts greatly accelerate this process. The transformation of gaseous ammonia into potassium amide proceeds rapidly at 300 °C.

Potassium metal along with a crown ether (18-crown-6 or 15-crown-5) in THF forms an alkalide composed of $K^-K^+(crown)_n$ that can be used in deprotonation reactions to generate ϒ-lactone enolates [19]. The alkalide with 15-crown-5 was shown to be more stable [20]. Alkalides of NaK have been studied recently and are presumed to exist as a K^+Na^-(15-crown-5) ionic pair [21].

Potassium reduces oxides, hydroxides, and salts of many heavy metals to the metallic state, and at high temperature it decomposes silicates (e.g., glass, porcelain, and mica).

Potassium and cesium react violently with Teflon equipment even under inert atmosphere; therefore, Teflon-coated stirbars or gaskets in equipment or valves should not be allowed to contact the metal.

1.2. Production

Degussa's electrolytic process for producing relatively pure potassium metal in the Castner cell was perfected in the late 1920s. This method employed an electrolyte containing 66 % KOH, 19 % K_2CO_3, and 15 % KCl. Later, a salt mixture (*mp* ca. 600 °C) of potassium chloride and potassium fluoride containing a small percentage of potassium carbonate was utilized [22]. Electrolysis of molten salt by the Downs process (1921) was developed into an industrial process for the manufacture of sodium, but corresponding efforts in the case of potassium have been unsuccessful.

In the industrial production of potassium metal, a thermal process is preferred over electrolysis because potassium reacts with the carbon electrodes in electrolysis.

$$KCl + Na \rightarrow K + NaCl$$

Reduction of potassium chloride with sodium metal was introduced in the 1950s by Mine Safety Appliance Company [23]. This process can produce from the same installation either high-purity potassium metal or potassium – sodium alloys of specified compositions. Sodium metal and molten potassium chloride are combined and a metal – vapor mixture of sodium and potassium is fractionated with a column. Sodium chloride produced from the reaction is drained off. Because potassium vapor is continuously withdrawn from the reaction zone, the equilibrium is shifted to the thermodynamically unfavorable potassium side.

The Griesheimer process, which was commonly employed in the past, is thermodynamically favorable starting from potassium fluoride and calcium carbide [24]. This thermal process is used in Baroda, Gujarat for consumption of potassium in the Heavy Water Plant operated by the Department of Atomic Energy in India. The endothermic reaction is presumably more complex than suggested by the simple chemical equation:

$$2\,KF + CaC_2 \rightarrow 2\,K + CaF_2 + 2\,C$$

Other thermal processes, in which potassium carbonate, caustic alkali, potassium fluoride, and potassium sulfate are treated with carbon, iron, silicon, or other reducing agents, have no commercial importance [25], [26], [27], [28], [29].

Potassium is commercially available with a purity of greater than 99.0 % [30] but very little is shipped as solid potassium metal. The preferred industrial compound is the alloy of sodium and potassium.

1.3. Handling and Occupational Safety

Potassium is packaged in steel or stainless steel drums and cylinders under a nitrogen atmosphere. It is classified as a substance which in contact with water, emits flammable gases. Transport regulations for potassium are as follows: [31]

UN No.	2257
Classification	4.3, PG I

Potassium is hazardous due to its rapid reaction with moisture in mucous membranes and skin. The potassium hydroxide formed on water contact is severely corrosive and can cause severe burns. When handling potassium, gloves and a nonflammable apron (leather is best) should be worn along with protective goggles and face shield. Where the potential exists for airborne exposure to potassium or potassium combustion products, an approved respirator equipped with particulate filters should be worn.

Potassium is highly flammable and reacts with water or moist air to form potassium hydroxide and hydrogen. The high heat of reaction causes the potassium to melt and spray, and it also ignites the released hydrogen. Because burning potassium is difficult to extinguish, conventional fire extinguishers are unsuitable. Such fires should be extinguished with a suitable dry powder mixture, dry sodium chloride, potassium chloride, water-free soda, dry sand, cement or Ansul's Met-L-X [32]. The use of foam extinguishers, carbon dioxide extinguishers, and halogenated hydrocarbons (e.g., carbon

tetrachloride) should be avoided.

Potassium should be stored in an inert atmosphere (argon or nitrogen) or under a high-boiling hydrocarbon (for limited storage periods). Small quantities can be kept in glass bottles under an inert atmosphere. Potassium stored under petroleum or other hydrocarbons can form the peroxide and superoxide at room temperature, which may provoke a massive explosion when the corresponding incrustation is removed (as by cutting). Potassium incrusted with a yellow oxide or peroxide layer should be destroyed in small quantities by careful, controlled disposal [33]. Small amounts of potassium residues (in containers, for example) may be dissolved in *tert*-butanol or other high-boiling alcohols [34]. The resulting alkoxide is destroyed by careful addition of methanol followed by water. The aqueous caustic potassium waste is then discarded in accordance with local regulations.

[Top of Page]

2. Potassium Alloys

Potassium forms alloys and, in some cases, intermetallic compounds with several metals (e.g., Na, Zn, Cd, Hg, In, Tl, Sn, Pb, and Bi). These alloys and intermetallic compounds are reactive substances, but are generally less reactive than free potassium metal. Except for alloys of sodium and potassium, intermetallic compounds are also less ductile than pure potassium metal.

When combined with either rubidium or cesium, potassium forms solid solutions over the entire range of binary compositions. The formation of solid solutions between potassium and metals from other groups in the Periodic Table is limited.

Liquid potassium amalgam with a low potassium concentration (ca. 0.3 % K) forms during the electrolysis of aqueous potassium chloride solutions in mercury cells.

Various alloys in the potassium – sodium system (Fig. 1) have achieved commercial importance, especially the liquid alloy containing ca. 78 % potassium (called “NaK alloy” or “nack” in the USA). Potassium – sodium alloys are liquid over a wide range of composition (ca. 40 – 90 wt % of potassium).

Figure 1. Sodium – potassium phase diagram [35]

2.1. Properties of NaK Alloy

The eutectic composition, with a eutectic temperature of –12.6 °C, contains 77.8 wt % K (corresponding to 66 atom % K). Na_2K is the only intermetallic compound existing with certainty in the sodium – potassium system (peritectic temperature 6.90 °C). The solubility of potassium in sodium at temperatures above 7 °C is given by the expression (57.1 – 0.586 *t*) wt %, where *t* is the temperature in °C [36]. Other physical properties follow: [37]

Composition	77.8 wt % K, 22.2 wt % Na
mp	–12.6 °C
bp (estimate)	785 °C
Electrical resistance	
at *mp*	33.5 μΩ · cm
at 20 °C	38.0 μΩ · cm
Density	
at 20 °C	0.867 g/cm^3
at 100 °C	0.855 g/cm^3
at 550 °C	0.749 g/cm^3
Thermal conductivity	
at 20 °C	2.18×10^{-3} W m^{-1} K^{-1}
at 550 °C	2.62×10^{-3} W m^{-1} K^{-1}
Specific heat	
at *mp*	0.975 J g^{-1} K^{-1}
at 100 °C	0.937 J g^{-1} K^{-1}

Trace impurities found in NaK alloys are H, C, N, O, OH, Cl, Ca, and Fe (together with its alloying partners in steels), as well as lead and other heavy metals. Metallic impurities are mainly introduced during the blending of potassium with sodium containing impurities. Purification of NaK alloys is performed (as with potassium) in a closed purification installation involving prepurification and subsequent distillation [38], [39]

2.2. Production of NaK Alloy

Alloys of potassium and sodium can be prepared by several methods:

1. Pure potassium and sodium metals can be melted together in an inert atmosphere or under an inert hydrocarbon
2. Various compositions of NaK can be prepared continuously from potassium chloride and sodium metal
3. An electrolytic process in a Castner crucible is a viable alternative for producing the alloy, in contrast to pure potassium metal

2.3. Handling and Occupational Safety of NaK Alloy

Commercial potassium – sodium alloys (see Potassium Alloys) are shipped in airtight steel cylinders equipped with internal piping and valves. In the United States, it is shipped in stainless steel or carbon steel containers containing 0.5, 14, 75, 84, 90, or 340 kg. Transport regulations for potassium – sodium alloys are as follows [40]:

Physical state	liquid at room temperature
UN No.	1422
Physical state	solid
UN No.	3404
Classification	4.3 PG I

Potassium – sodium alloys are highly flammable and react with water or moist air to form potassium hydroxide and hydrogen, which may ignite. The dangers are increased because spilled metal may flow toward reactive materials since these alloys are liquid at ambient temperature. The technology for handling NaK on a large scale from ambient temperature to ca. 825 °C is well developed, and equipment is available commercially for pumping and metering NaK safely and accurately on any scale. Handling information and a safety and handling video are available from BASF Corporation.

Potassium – sodium alloys rapidly react with moisture in mucous membranes and skin. The potassium hydroxide formed upon water contact is highly irritating and leads to burns and skin cauterization. When handling cylinders containing potassium – sodium alloy, gloves and a nonflammable apron (leather is best) should be worn along with protective goggles and face shield. Where the potential exists for airborne exposure to the alloy or combustion products, an approved respirator equipped with appropriate filters should be worn.

NaK fires should be extinguished with a suitable dry powder mixture, dry sodium chloride, potassium chloride, water-free soda, dry sand, cement, or Ansul's Met-L-X [41]. The use of foam extinguishers, carbon dioxide extinguishers, and halogenated extinguishing agents (e.g., carbon tetrachloride) should be avoided.

Potassium – sodium alloys should be stored in an unbreakable container under an inert atmosphere (argon or nitrogen). It is not recommended to store potassium – sodium alloy under petroleum or other hydrocarbons, since potassium superoxide can form from dissolved oxygen. Potassium superoxide is insoluble in NaK and may provoke an explosion when physically manipulated in contact with organic material.

[Top of Page]

3. Uses of Potassium and Potassium Compounds

The understanding of potassium chemistry has been greatly expanded over the last 40 – 50 years [42], [43], [44], [45], [46], [47], [48] and this has led to numerous applications of potassium compounds. Potassium, sodium – potassium alloys, and potassium compounds (alkoxides, amides, and hydride) are extensively used in academia and industrially to synthesize both organic and inorganic compounds.

3.1. Potassium and NaK Alloy

In general, organopotassium compounds, i.e., those with a potassium – carbon bond, are not thermally stable and so must be formed at subambient temperature and used immediately [49]. Potassium vapor was used for doping of single-walled carbon nanotubes [50] and superfulleride thin films [51]. These materials have been studied for their electronic properties as quantum dots. Potassium-doped carbon nanotubes were also found to absorb hydrogen at ambient temperature and release it at higher temperature [52]. These compounds may find use for hydrogen storage, since the sorption – desorption cycle can be repeated.

Potassium – Sodium Alloys (NaK). On an industrial scale, the chemistry of potassium is most easily conducted by using the liquid alloy of sodium and potassium. Sodium – potassium alloys are used for performing reactions of potassium metal in organic synthesis. For chemical reactions involving unstable intermediates such as carbanions and free radicals, NaK is preferred to the individual metals due to its liquid state down to –12 °C. Additionally, NaK alloy is used in applications that exploit its unique physical properties.

The advantages of NaK compared to Na or K are:

- Higher reactivity than solid alkali metals at ambient temperature
- Higher surface area of reactive metal than either sodium or potassium
- Elimination of the need to produce and handle reactive metal dispersions

– Easily applied to solid supports

Physical Applications. In addition to easier handling, the unique physical properties of NaK led to its use as a heat-exchange fluid in nuclear reactors [53], [54], [55], [56]. Although the market for NaK in the nuclear industry is insignificant, the favorable thermal properties are still being exploited in other heat-exchange applications [57], such as a cooling liquid in hollow valve stems [58] and in solar power generators [59]. The electrical conductivity and the wide range of compositions in the liquid state render the NaK alloys ideal for use in nonaqueous batteries, [60] high-temperature thermostats, and as a hydraulic fluid [61].

An interesting application of NaK may involve both its reduction and alloying capacities; the treatment of brass plumbing fixtures with NaK removes Pb from the surface and decreases the leaching of Pb into water during use [62].

Chemical Applications. Sodium – potassium alloy is used in a number of industrial applications, such as alkylation, isomerization, condensation, and transesterification reactions. One of the largest commercial uses of NaK as a catalyst is for side-chain alkylation of toluene and xylenes [63]. An example is the side-chain alkylation of toluene to form isobutylbenzene, a starting material for the synthesis of ibuprofen. The synergistic effect of the two alkali metals has been studied [64].

Side-chain alkylation of xylene followed by isomerization and oxidation yields naphthalenedicarboxylate [65], a specialty monomer. In these applications, the reactivity of the liquid metal is increased by dispersion on a solid support.

NaK has also been used extensively for isomerization of α-olefins to internal olefins [66].

Industrially, this process is used to isomerize norbornene for use in the synthesis of EPDM rubbers.

NaK alloys have found applications in dehydrogenation [67], free-radical [68], condensation [69], [70], [71], [72], and polymerization [73] reactions. Polymerization of alkylsilicon trichlorides with NaK generates Si – Si bonded materials [74]. Additionally, NaK has been used for the synthesis of polycarbynes [75], in the derivatization of poly(isobutylene-*tert*-butyl methacrylate) block copolymers [76] and as initiator for anionic polymerization [77].

As a reducing agent, NaK can be used to reduce metal halides to highly reactive metal powders [78]. Potassium complexes with crown ethers have also been used in metal-salt reductions [79]. For example, lanthanide nanoparticles have been prepared by reduction of the salts with NaK(crown ether) complexes [80]. Synthetic utility of NaK includes reduction of organic functional groups such as arenes, ketones, aldehydes, and alkyl halides [81], [82] and reductive cleavage of functional groups containing C–X, C–O, and O–S bonds [83], [84], [85], [86], [87].

The complete dechlorination of polyhalogenated hydrocarbons is a difficult process but extremely important for the environmental remediation of contaminated waste and soil. Hexachlorobenzene was efficiently dechlorinated at nearly 100 % conversion in 30 min with NaK alloy due to its high reactivity [88].

Since NaK is a liquid at room temperature it has been used as an efficient impurity scavenger in both organic liquids and gases. Examples are the removal of acetylenic and allenic contaminants [89] and purifying gas streams for semiconductor processes [90]. This application for gas purification is no longer recommended because of the explosion [91] hazards due to KO_2 formation.

An interesting use of NaK for a consumer product is the interesterification of vegetable oil to margarine [92] and interesterification of tallow with cotton seed oil to improve the pour and clarification temperatures [93].

Potassium Graphite (C_8K). Potassium, rubidium, and cesium react with graphite (⟶ Carbon) and activated carbon to form compounds with the following formulas: C_8M, $C_{24}M$, $C_{36}M$, $C_{48}M$, and $C_{60}M$ [94]. C_8K corresponds to all carbon layers separated by a layer of potassium. In $C_{24}K$, $C_{36}K$, etc., intercalation occurs in each second, third, fourth, etc., interlamellar graphite spacing. At these higher stages of intercalation the structure is less ordered than that of C_8K (⟶ Carbon – Graphite Intercalation Compounds). Potassium graphite [12081-88-8] (C_8K) in the form of bronze-colored flakes is prepared by melting potassium over graphite at 120 – 150 °C under an inert atmosphere.

Potassium graphite is a powerful solid reducing agent because the free electrons from the ionized potassium are trapped within the graphite lattice. In packed columns or beds, it can effectively eliminate undesirable organic contaminants such as halogenated hydrocarbon impurities from gas streams and liquid solutions. The scope of its reducing reactions include [94], [95] Birch-type reactions of α, β-unsaturated ketones, carboxylic acids, and Schiff's bases; reductive cleavage of vinylic and allylic sulfones; selective alkylation of aliphatic esters, imines, and nitriles; reductive decyanation of nitriles; and reduction of glycosyl halides to glycols [96].

Potassium graphite has also been used to prepare active metals supported on graphite (Gr) by reduction of the metal salt in THF: [94], [97] Zn – Gr [69704-06-9] for Reformatsky reactions, Sn – Gr [89248-61-3] for allylic organometallics, Ti – Gr [6970-05-8] for coupling carbonyl compounds, Fe – Gr [55957-21-6] for debromination, Pd – Gr [59873-73-3] for vinylic and allylic substitution, and Pd – Gr, Ni – Gr [59873-69-7] for hydrogenation. Potassium graphite has been used to prepare chromium carbenes [98] and has also been applied in polymerization reactions [99]. Potassium graphite or similar intercalation compounds may have applications in pyrotechnic compositions [100].

Potassium on Alumina and Silica Support. Finely dispersed potassium on aluminum oxide has been used in double-bond isomerizations and as a metalating agent [101]. Methods to apply and use alkali metals on silica support have been studied [102].

3.2. Potassium Hydride

Potassium hydride [7693-26-7], KH, is made from potassium metal and hydrogen gas at ca. 200 °C in an oil dispersion or at lower temperatures with a catalyst [103] (⟶ Hydrides – Potassium Hydride). The principal supplier is Pressure Chemical Company, Pittsburgh, PA (USA).

The synthesis [104] and use of KH as a base and as a nucleophile is reviewed elsewhere [105]. Compared to NaH or LiH, KH [106], [107] is an effective reagent for ketone enolization reactions, although soluble potassium bases (such as potassium hexamethyldisilazane) are the best choice for kinetic deprotonation. Potassium hydride has been used as an initiator for anionic polymerization of oxiranes [108]. A practical cycling hydrogen storage medium was prepared by addition of KH to a mixture of NaH and $NaAlH_4$ doped with Ti [109].

A noteworthy development is conversion of the basic character of potassium hydride to a hydridic character by complexing with alkoxyboranes and alkylboranes. The potassium borohydride complexes formed vary from mild to strong reducing agents and are used primarily in the pharmaceutical industry. Potassium triethylborohydride [22560-21-0], $KB[C_2H_5]_3H$, potassium tri-*sec*-butylborohydride [54575-50-7], $KB[CH(CH_3)C_2H_5]_3H$, and potassium trisamylborohydride [67966-25-0], $KB[CH(CH_3)CH(CH_3)_2]_3H$, are made by the reaction of KH with triethylborane [97-94-4], tri-*sec*-butylborane [1113-78-6], and trisamylborane [32327-52-9], respectively, in THF. Potassium triisopropoxyborohydride [42278-67-1] can be made by the reaction of KH with isopropyl borate [5419-55-6] [110] and is much less reactive.

The potassium trialkylborohydrides find a variety of uses as selective reducing agents [111], [112]. Potassium triethylborohydride is a strong reducing agent that rapidly reduces a number of functional groups [113]. For example, disulfides are reduced to thiols, epoxides are reduced to give the more substituted alcohol, and primary bromides and iodides are reduced to the corresponding hydrocarbon.

Because of its bulky nature, potassium tri-sec-butylborohydride (KTSBBH) exhibits high stereoselectivity in the reduction of

hindered cyclohexenones [114]. An example of high diastereofacial stereoselectivity achieved using potassium tri-sec-butylborohydride is the reduction of optically pure acyl lactones to protected *syn*-diols [115]. In comparison, reduction with sodium borohydride gave a *syn*:*anti* ratio of 35:65.

Regioselective reduction of unsymmetrical cyclic anhydrides by trialkylborohydrides affords lactones [116]. Potassium tri-*sec*-butylborohydride cleanly reduces α, β-unsaturated enones in a 1,4-addition to give ketones [117], [118] In addition, potassium trialkylborohydrides and potassium triisopropoxyborohydride have been used in organometallic synthesis [119].

3.3. Potassium Bases

Another major application of potassium metal involves preparing potassium bases by treating the metal with alcohols and amines (⟶ Alcohols, Aliphatic – Alkoxides).

3.3.1. *Potassium Alkoxides*

Potassium alkoxides (also called alcoholates) are moderately strong bases that are used in countless drug- and chemical-synthesis applications such as alkylation, arylation, acylation, solvolysis of esters, condensation, elimination, isomerization, rearrangements, transfer hydrogenation, Wittig reactions, and redox reactions. Many potassium bases are commercially produced on the multitonne scale [120]. The most commonly used bases are potassium methylate [865-33-8], potassium *tert*-butylate (KTB) [865-47-4], and potassium *tert*-amylate (KTA) [41233-93-6]. Annual world consumption of potassium alkoxides (as $KOCH_3$) exceeds 2000 t. The bases derived from tertiary alcohols offer such advantages as strength (pK_a = 18), solubility (see Table 3), selectivity (due to the bulky *tert*-alkyl groups), and stability (because of the lack of α-protons). In addition, KTB and KTA powder have long shelf lives of several years when stored under an inert atmosphere.

Table 3. Solubility of KTA and KTB at 25 °C (wt %)

Solvent	KTA	KTB
Toluene	36	2.3
Cyclohexane	36	0.4
Hexane	30	0.3
2-Methoxyethyl ether	47	42
Tetrahydrofuran	54	44

The base strength can be varied with choice of solvent and the structure of the alcohol. In DMSO, the ion aggregates are solvated, thus increasing the basicity. As alkyl groups are added to the alcohol, the alcoholate becomes a stronger base compared to primary alcoholates and hydroxide. Furthermore, the higher base strength and steric bulk of the tertiary alcoholates influence the speed, selectivity, and specificity.

KTB and KTA are usually preferred over NaH for deprotonation reactions because they have good solubility, leave no oil residue, and produce no hydrogen. Selective deprotonation can be achieved with KTB due to the steric hindrance provided by the tertiary butyl group. The following examples of potassium alkoxides illustrate the diverse applications of these bases.

Aryl- or heteroaryluracils, useful as herbicides, were prepared with substantially increased yields over previous methods by cycloaddition of isocyanates in the presence of 0.1 – 0.3 equivalents of KTB in DMF or DMSO [121].

By a Wittig reaction, cephalosporin derivatives were prepared in 75 % yield via conversion of the phosphonium bromide to the corresponding ylide with KTB, then treating the ylide with an aldehyde [122].

The hydrocarbon solubility of potassium tert-amylate (KTA) gives it an advantage over sodium and potassium alcoholates derived from *tert*-butanol or primary alcohols. In the synthesis of α-chloroketones from amino acid phenyl esters, a sulfur ylide was formed by deprotonation with KTA. The amount of desired product was dramatically increased with KTA versus NaH [123].

Base	Ratio
KTA	>99:1
NaH	50:50

For higher base strength, mixed metal reagents derived from organolithium compounds and potassium alkoxides (Superbase or LICKOR reagent [124]) can provide unique reactivity and selectivity. Superbases are capable of deprotonating compounds of very low acidity, to about pK_a = 45. *ortho,ortho′*-Disubstituted diphenylacetylenes were prepared by use of a superbase made from n-butyllithium and KTB. The products were prepared in moderate yields but with high regioselectivity [125].

A growing use of potassium methoxide is in the interesterification of vegetable oils and waste cooking oil to make biodiesel [126]. Typically, potassium methoxide is a more efficient catalyst that NaOH or KOH for this process.

3.3.2. *Potassium Amides*

The most useful of the potassium amides is potassium hexamethyldisilazane [40949-94-8] (KHMDS), $KN[Si(CH_3)_3]_2$. This strong (pK_a = 28), extremely soluble, stable and nonnucleophilic potassium amide base is available in commercial quantities [127] in THF, toluene, and 1,3,5-trimethylbenzene solutions. KHMDS is ideal for regio- and stereospecific deprotonation and has demonstrated benefits for reactions involving kinetic enolates [128], alkylation and acylation [129], Wittig reaction [130], epoxidation [131], Ireland – Claisen rearrangement [132], [133], isomerization [134], [135], Darzen reaction, [136] Dieckmann condensation [137], cyclization [138], chain [139]/ring expansion [140], and elimination [141].

KHMDS efficiently forms the kinetic enolate of a carbonyl compound with α-hydrogen atoms [142]. Potassium enolates are highly reactive [143], for example, a potassium oxindol enolate reacted about ten times faster than the corresponding lithium enolate [144].

The cation can have an effect on the subsequent selectivity of the enolate alkylation. Sodium and lithium enolates yield primarily C-alkylation products while potassium enolates O-alkylation. For example, in the multikilogram synthesis of intermediates for production of LFA-1 inhibitors, a bis-lactam was deprotonated with KHMDS and O-alkylated with $(EtO)_2POCl$ [145]. Equilibration to thermodynamic enolates by warming to ambient temperature allowed O alkylation of an enolate to prepare a Claisen precursor [146].

A Wittig reaction is an effective way to replace a carbonyl group with an olefinic residue [147]. Both NaHMDS and KHMDS have been used effectively to generate phosphorous ylides under lithium-free conditions to attain high Z selectivity [148]. KHMDS was the reagent of choice in the Wittig synthesis of Z trisubstituted allylic alcohols [149]. A synthesis of a glaucoma drug used KHMDS in the Wittig reaction to deliver 97.8 % *cis* product along with only 2.2 % *trans* product, whereas KTB gave 3.5 % *trans* [150].

Vinylaziridines are required for a precursor to the synthesis of frog alkaloids [151]. Use of KHMDS as the base gave the desired product with an *E*:*Z* ratio of 1:17.

The anionic version of the oxy-Cope rearrangement proceeds more rapidly and is called the oxyanionic Cope rearrangement. In the synthesis of taxol derivatives, KHMDS was used in the anionic oxy-Cope rearrangement to give optically pure tricyclic compounds [152].

Other potassium amides such as potassium diisopropylamide [67459-71-6], potassium 2,2,6,6-tetramethylpiperidide [110426-49-8], and potassium 3-aminopropylamide [56038-00-7] ($KNHCH_2CH_2CH_2NH_2$, KAPA) have not yet found widespread application. Due to their tendency to decompose or react with solvent, these reagents are usually prepared and used in situ. KAPA, pK_a 35, can be prepared by the reaction of 1,3-diaminopropane with potassium metal or

potassium hydride [153], [154], [155]. However, due to the extremely unstable nature of this amide, in situ use is strongly advised. KAPA is extremely effective in converting internal acetylenes to the terminal isomers, which are stabilized as potassium acetylides. For example, KAPA isomerizes 3-methyl-4-nonyne to 7-methyl-1-nonyne in about 1 min at 0 °C [156].

3.4. Potassium Superoxide

Potassium behaves similarly to rubidium and cesium on oxidation by oxygen, forming potassium superoxide [12030-88-5], KO_2. The Mine Safety Appliances Company first developed potassium superoxide for use as an oxygen source in self-contained breathing equipment, since it liberates oxygen in contact with exhaled moisture and carbon dioxide [157].

Yellow potassium superoxide forms on the surface of potassium metal on exposure to air or oxygen dissolved in solvents. Extreme care must be taken when this yellow solid is found on potassium stored in hydrocarbon oils, because explosions have occurred when the yellow KO_2 is disturbed, such as by cutting or scraping.

Since potassium superoxide is a strong oxidizing agent, its utility in organic synthesis is limited but has been briefly studied. The unique chemical behavior of KO_2 is a result of its dual character as a radical anion and a strong oxidizing agent [158], [159]. The reactivity and solubility of KO_2 is greatly enhanced by crown ethers [160]. Its usefulness in furnishing oxygen anions is demonstrated by its applications in S_N2-type reactions to displace methanesulfonate and bromide groups [161], the oxidation of benzylic methylene compounds to ketones [162], and the synthesis of a-hydroxyketones from ketones [163]. Appropriate caution must be taken due to the hazard associated with potassium superoxide in the presence of organic materials. For example, acetone vapors have exploded in the presence of KO_2.

1. Introduction

1.1. Occurrence

Potassium occurs in nature only in the form of its compounds. It is one of the ten most common elements in the earth's crust. Several widely distributed silicate minerals contain potassium, in particular, the feldspars (→ Silicates) and micas (→ Mica). The weathering of these minerals produces soluble potassium compounds, which are present in seawater and occur in extensive salt deposits. Potassium is important in the metabolism of plants and animals, and is therefore found in ash from plant materials and in the bodies of animals. Potassium compounds are obtained almost entirely by the mining of salt deposits.

1.2. History

Before the discovery and exploitation of potassium salt deposits, the production of potassium compounds consisted almost entirely of potash (K_2CO_3) obtained from natural sources such as wood ash, residues from distilleries, Bengal saltpeter, wool grease, and mother liquors from sea salt production. Quantities were small and were used only for the production of soap, glass, and explosives.

In 1840, J. von Liebig laid the foundations of the theory of mineral fertilizers in his paper "The Application of Organic Chemistry to Agriculture and Physiology" (→ Fertilizers, Chap. 2.). This spread the knowledge that potassium was one of the most important plant nutrition elements. In 1851, some deep mine workings in Stassfurt struck minerals containing potassium and magnesium, although these could not be used as fertilizers. In 1861, Adolph Frank started the first plant using the process that he developed for producing from carnallite a potassium salt that could be employed as a fertilizer. This soon led to the development of other processes and to the establishment of many potash mines and works. Many attempts were made up to the end of World War I to hinder the building of new factories in Germany, which had a world monopoly in the production of potash fertilizers, and attempts were made to ration production and supply, and to regulate prices. In spite of this, 69 factories were in existence in 1910, and 198 in 1918. When World War I ended, Alsace was returned to France, and the potash works that were built there shortly after 1900 became French property, so that Germany lost her monopoly in potash.

The German national assembly of 1919 enacted the potash regulations and the so-called closure order, which reduced the number of operating factories to 29 by the year 1938. This also caused production to be concentrated in a few large potash companies [17, 18].

After the end of World War II, ca. 60 % of German production capacity went to the area that was later to become the German Democratic Republic, and became the VEB Kombinat Kali. After German unification in 1990, the newly formed Mitteldeutsche Kali AG took over these

operations. In the Federal Republic of Germany, several groups of works were formed, leading in 1970 to the formation of the company Kali und Salz AG following a series of amalgamations. This company owns seven potash works, all located in the former Federal Republic of Germany [19, 20].

Most of the French potash works in Alsace were nationalized after World War I. During World War II, production was greatly increased. Several of the deposits have now become exhausted, and many of the works have been closed. Production has been concentrated in two large works, although these are likely to be closed down soon after the end of this century [21].

Potash production in Spain began in 1926 with the start up of a factory in Catalonia. Other factories were established later both there and in Navarra.

The kainite deposits in Sicily have been worked since 1959 – 1960; the salts are used for potassium sulfate production [22].

The Soviet Union began potash production in 1931 at a plant in the Northern Urals. In 1939, plants that had been operating in Eastern Poland since 1920 were taken over by the Soviet Union. In 1963, the first plant was started to exploit a very extensive deposit in White Russia. The CIS today has several large operations in the Urals and White Russia, giving it the largest capacity of all potash-producing countries.

In the United States, potash production began during World War I because the United States economy could no longer buy German potash fertilizers. Potassium salts were obtained from Searles Lake in California and in northern Nebraska. Most of these operations ceased production in the 1920s. After the discovery of potash deposits in the area of Carlsbad, New Mexico, a large number of potash works were founded since 1931 [23]. Since the foundation of the Canadian potash industry, which has the United States as its main outlet, the number of works in the Carlsbad region and their production rate have continually declined. New potash works were started in southern Utah at Moab in 1964 and at the Great Salt Lake in 1970 [24].

The most important potash deposit in North America was discovered during World War II in Saskatchewan, Canada. After initial problems due to its great depth and the presence of water-bearing overlying rock, which was difficult to deal with, several potash works were founded in the early 1960s, and today Canada is second only to the CIS as a potash producer. Two more potash plants were established in the 1980s in New Brunswick on the east coast of Canada.

In 1986, a potash plant began production at Sergipe in Brazil.

In 1974, a potash mine was opened in Yorkshire, United Kingdom.

Potash production in Palestine began on the north bank of the Dead Sea in 1931. Potash plants have now been producing since 1952 at the southern end on the Israeli side and since 1982 on the Jordanian side.

Potash ores are treated today by three basic processes: leaching – crystallization, flotation, and electrostatic treatment. Gravity separation is of minor importance because of the small density differences between salt minerals.

The oldest process is leaching – crystallization. In this process, salt solutions were originally cooled in open vessels. Vacuum cooling of the solutions in crystallizers was introduced in 1918 in the United States, so that much less energy was required and cooling times were reduced from days or weeks to minutes. Flotation was introduced in 1935 in the United States. This proved so efficient, especially for the treatment of sylvinite ores, that it is now the main potash treatment process worldwide. The electrostatic process was first used on a large scale in the German potash industry in 1974. It is now widely used in Germany for treating complex hard salts.

2. Potash Salt Deposits

2.1. Minerals

Potash salt deposits were formed by the evaporation of seawater [25]. Their composition is often affected by secondary changes in the primary mineral deposits. More than 40 salt minerals are now known, which contain some or all of the small number of cations Na^+, K^+, Mg^{2+}, and Ca^{2+}; the anions Cl^- and SO_4^{2-}; and occasionally Fe^{2+} and BO_3^{3-}, as well. Most of these are listed in Table 1 [26].

The more important salt minerals are halite, anhydrite, sylvite, carnallite, kieserite, poly-

Table 1. Principal salt minerals

Mineral	CAS registry no.	Formula	Crystal system/ crystal class	Refractive indices $n_\alpha : n_\beta : n_\gamma$ or $n_{\mathrm{opt.}} : n_{\mathrm{C}}$; optical activity	Density, g/cm^3	Hardness (Mohs)
Anhydrite	[*14798-04-0*]	$CaSO_4$	rhombic D_{2h}-mmm	1.570 : 1 .575 : 1.614 opt. +	2.96	3.8
Ascharite	[*13768-64-4*]	$Mg_2[B_2O_5] \cdot H_2O$	monoclinic C_{2h}-2/m	1.575 : 1.646 : 1.650 opt. −	2.70	3

halite, langbeinite, and kainite. Gypsum occurs at the edges of salt deposits and in the overlying strata. Bischofite, tachhydrite, glauberite, thenardite, glaserite, and leonite occur additionally in some deposits [4, 27, 28].

Other minerals, not described in detail here, are useful in elucidating difficult geological questions with regard to the origin of salt deposits. In special geochemical investigations, small amounts (ppm) of Rb^+ and Cs^+ in place of K^+; Sr^{2+} replacing Ca^{2+}; Mn^{2+} replacing Fe^{2+}; Br^- replacing Cl^-; etc., are important [29, 30]. The individual minerals can be identified microscopically (grains or thin sections) and by X-ray analysis.

Potassium salt deposits always consist of a combination of several minerals (Table 2). The German term *Hartsalz* (hard salt) refers to the greater hardness of sulfate-containing potash minerals in potash deposits.

Table 2. Marine salt rocks: mineral constituents ∗

Salt rock	Main components	Secondary components
Rock salt	Na	A, Po, Ki, La, clay minerals, etc.
Anhydrite	A	Na, Dol, Mag, gypsum, Sy, C, clay minerals, borates
Carnallitite	C, Na	Ki, Sy, A
Sylvinite	Sy, Na	C, Ki, A
Hard salt		
kieseritic	Na, Ki, Sy	C, A, La, Po, borates
langbeinitic	Na, La	Ki, A, Sy, C
anhydritic	Na, Sy, A	Ki, C
Kainitite	Na, Kai	Ki, Sy, C
Bischofitite	Bi, C and/or Ta	Na, Ki, Po, A, borates
Tachhydritite	Ta, Bi	C, Na
Claystone	Clay minerals, quartz, mica, A, Dol, Mag	Na, Sy, C, Bi, Ta, La, coenenite, rinneite

∗ Abbreviations: A = anhydrite; Bi = bischofite; C = carnallite; Dol = dolomite; Kai = kainite; Ki = kieserite; La = langbeinite; Mag = magnesite; Na = halite; Po = polyhalite; Sy = sylvite; Ta = tachhydrite.

2.2. Geology of Potash Deposits

Potash deposits occur worldwide in almost all geological systems. The most important deposits were formed in the Devonian, Carboniferous, Permian, Cretaceous, and Tertiary periods [4, 25, 27, 31–37]. All major potash deposits are of marine origin. Bodies of seawater became isolated from the open ocean when bars formed under the water surface, and under arid climatic conditions, the seawater became concentrated, finally depositing the dissolved salts. The important feature is that exchange between normal seawater and concentrated salt solution generally does not occur. During sedimentation, the less soluble salts were deposited first, and the most soluble salts last. In most salt-forming sea basins, this process was repeated many times, resulting in cyclical salt formation [36, 38].

Table 3. Important potash deposits, mineral composition [a], geologic age [b]

Country	Geological age									
	Rect	Plei	Tert	Cret	Jura	Perm	Carb	Dev	Sil	Camb
Australia	B									
Brazil				SC

Spain			S							
Thailand				CS						
United States	B					SL	S	SC	S	

[a] S = sylvinite; C = carnallite; H = hard salt; L = langbeinite; K = kainite; B = brine.
[b] Rect = recent; Plei = Pleistocene; Tert = Tertiary; Cret = Cretaceous; Jura = Jurassic; Perm = Permian; Carb = Carboniferous; Dev = Devonian; Sil = Silurian; Camb = Cambrian.

A complete salt deposition cycle begins with basic carbonates (limestone, dolomite, and sometimes magnesite), followed by sulfates (gypsum and anhydrite), rock salt, and finally potassium and magnesium salts (Table 1). Intermediate layers of clay sediments are the result of repeated influxes of fresh water, which can lead to partial redissolution of the salt deposits. Also, eolian (airborne) transportation into the basin can occur. A recent example of a salt deposition basin is provided by the Kara-Bugas, a lagoon on the eastern side of the Caspian Sea.

In the course of the earth's history, the deposited salts underwent many changes, often leading to the formation of a modified mineral constitution. The original formations were affected by relatively low-temperature thermal

and hydraulic metamorphoses, and sometimes by volcanic action, producing the mineral compositions that exist today (Table 2) [39,40].

Rock movements have changed the original horizontal stratification in many salt deposits. Salt migration, folding, and upward movement to form diapirs have led to tilting of the potash layer, sometimes to an acute angle; to thinning; or to local accumulation. As a result of movements, salt deposits often came into contact with groundwater and were partially or completely redissolved.

Table 3 lists the most important potash salt deposits, showing the main potash minerals present, the geological systems, and the geographical locations. Table 4 shows the distribution of potash deposits, with estimates of the reserves [4,37,41].

Table 4. Minable potash reserves in units of 10^6 t K_2O

Canada, Saskatchewan (conventional mining only)	4500 – 6000
New Brunswick	60 – 80
United States	100 – 150
Brazil	10 – 40
Chile and Peru	30 – 50
Congo	ca. 20
Germany	400 – 800
United Kingdom	30 – 50
Italy	10 – 20
France	ca. 20
Spain	20 – 30
CIS	2000 – 3000
Dead Sea (Israel and Jordan)	100 – 200
China	10 – 100
Thailand	up to 160
Laos	up to 20
World *	7500 – 10 000

* If reserves only extractable by solution mining are included (particularly those in Saskatchewan, but also including those in the CIS), the figure for the total minable reserves increases by a factor of 4 or 5. Other deposits of potash salts are either unimportant or of minor local importance compared with the above figures. These exist in Australia, Ethiopia, Iran, Libya, Morocco, Poland, and Tunisia.

The concept of a reserve presupposes the possibility of economical extraction, which depends on the presence of a useful potash content together with usable quantities of other materials. Other important factors are the type of deposit, a uniform and usable seam thickness at a depth that is neither too great nor too low (water problems), economic workability, the possibility of solution extraction, and above all, proximity to consumers and profitability. Losses incurred during the extraction process (10 – 20 %) must be deducted from the total size of the reserve.

The two largest known potash deposits in the world, which are in Saskatchewan (Canada) and White Russia, are of Devonian origin. The Permian deposits (Germany, United States, and CIS) were for a long period the classical salt deposits and were the most important potash reserves, but these lost their economic importance after World War II.

However, the known potential of extractable potash deposits is so large that the world supply is guaranteed for many hundreds of years.

Cambrian. In the central part of the Angara-Lena Trough, ca. 800 km north-northeast of Irkutsk (CIS) in the vast eastern Siberian basin, an evaporite series more than 2 km thick contains a potash deposit. A sylvinite series up to 28 m thick is situated at a depth of 600 – 900 m in the interior of this Nepa potash basin. At the edges it merges into carnallitite, with over- and underlying carnallite – halite. The potash content of the best sylvinite seam, up to 13 m thick, is 19 – 30 % K_2O, with an extremely low $MgCl_2$ content [4, 27,37].

Silurian. In the center of the Michigan basin is a sylvinite zone having a total thickness of 28 m within a 900-m-thick evaporite series of the Salina group covering an area of 34 000 km^2. A solution-mining pilot plant (see Section 3.3) is in operation [4,37].

Devonian. *Canada.* The western Canadian basin between the Rocky Mountains and Hudson Bay accomodates eight Devonian salt-bearing units, of which the Prairie Evaporite is the most important both in extent and in economic importance, having four potash seams, partly sylvinitic and partly carnallitic. The upper limit of the Prairie deposit is inclined to the south, beginning at a depth of 600 m in the northeast and ending at >3000 m in the southwest. Of the total area (ca. 200 000 km^2) of the potash seams, ca. 50 000 km^2 is extractable by mining. Other areas can only be exploited by solution mining. The clay-bearing sylvinites, each 3 – 5 m thick, contain 25 – 30 % K_2O, but no potassium magnesium sulfate. At present, ten plants are in operation [4,27,37].

United States. The potash deposit described above, which is of great importance for Canada, stretches across the border to Montana and North Dakota. The potash-bearing area covers more than 30 000 km^2, but because it is at a depth of >1000 m and up to 3500 m, extraction by conventional mining is impossible [4, 37].

CIS. The potash deposits of Soligorsk and Starobinsk lie within the Pripyat marshes, 25 000 km^2 in area, ca. 120 km south of Minsk and 800 km from the Baltic harbor of Ventspils. Potash extraction began in 1963, and output reached 4.2×10^6 t of K_2O by 1980. The Upper Salt is 3200 m thick and contains ca. 60 potash zones in the upper half. These can be grouped into four workable potash-bearing formations. Each of these consists of interbedded layers of salt clays, rock salt, sylvinite seams, and some carnallitite. Only stage II (thickness: 1.8 – 4.4 m, K_2O: 17.7 %, insolubles: 5 %) and the lower part of stage III (thickness: up to 2.8 m, K_2O: 13.4 – 16.4 %, insolubles: 9 %) are extracted. Potash is mined at depths of 350 – 950 m, where level seams with only slight deformation exist [4, 28, 37].

Carboniferous. *United States.* The potash deposit of the Paradox formation at Moab, Utah, is extracted by Cane Creek Mine. The valuable sylvinite deposit is at present extracted by solution mining. The extent of the salt deposit is ca. 25 000 km^2, of which 15 000 km^2 is potash bearing. It contains about ten potash seams, of which four are workable, containing sylvinite (25 % K_2O) and some carnallitite. The salt has been formed by tectonic action into anticlines, sometimes diapiric, stretching from northwest to southeast [4, 27, 37]. Because the deposit is undulating, conventional mining is complicated and made hazardous by the presence of oil and gas.

Canada. In the eastern provinces of Canada on the Atlantic coast (i.e., New Brunswick, Nova Scotia, and Newfoundland) are a number of small sedimentary basins with evaporites of the Lower Carboniferous Windsor group. Gypsum, anhydrite, and slightly to strongly folded rock salt are present, along with several mainly tectonically bounded small structures containing potash salts. In New Brunswick a high-quality sylvinite seam occurs that contains 25 – 30 % K_2O up to 40 m thick. At present, potash is extracted by PCA (Potash Corporation of America) 7 km north of Sussex at a depth of 460 – 760 m, and by PMC (Potacan Mining Corporation) 25 km south-southwest of Sussex at a depth of 600 – 1000 m [4, 27, 37].

Permian. The Permian period was one of immense salt accumulation, which took place in three vast evaporite basins: (1) the Central European Basin, (2) the East European Basin, and (3) the American Midcontinental Basin, as well as numerous smaller sedimentation areas in Europe, Asia, North and South America, and the Arctic [27].

1) *The Central European Basin* extends from Yorkshire to Central Poland and Lithuania, and from the River Main in northern Germany to the northern part of the North Sea [42]. In the Zechstein, seven sedimentation periods are distinguished, of which the three lowest–the Werra, Stassfurt, and Leine series–are of economic importance for potash extraction.
Germany. In the Werra and Fulda areas, the Hessen and Thuringia potash seams of the Werra series are mined (hard salt and carnallitite in level deposits at a depth of 400 – 1000 m with a thickness of 2 – 5 m, K_2O: 9 – 12 %). The Stassfurt potash seam of the Stassfurt series is mined in the Harz – Unstrut – Saale area (hard salt and carnallitite at a depth of 500 – 1000 m and a thickness of 5 m, K_2O: 20 %). The potash seams Ronnenberg and Riedel of the Leine series are mined in the Hanover area in salt diapirs (sylvinite in inclined deposits, depth: 350 – 1500 m, thickness: 2 –40 m, K_2O: 12 – 30 %). Hard salts of the Stassfurt series are at present extracted to only a minor extent. Finally, potash is mined on the Massif of Calvörde near Zielitz (depth: 600 – 900 m, Ronnenberg sylvinite inclined at <18 – 25°, thickness: up to 10 m, K_2O: 14 – 20 %) [4, 37].
United Kingdom. In Yorkshire, a level deposit of carnallitic sylvinite is extracted, which correlates with the German Riedel seam both petrographically and stratigraphically (average thickness: 5 m, K_2O: ca. 27 %, depth: 1100 m) [4] *The Netherlands.* In northeast Holland, the carnallitic potash

salts of the Leine series have been drilled at various places. The plans are to extract carnallitite by solution mining [4].
Poland. The Zechstein series in Poland correlates with that in Germany. The carnallitic formations of the Stassfurt seam have been drilled, and the Leine deposits also contain some carnallitite and sylvinite.

2) *The Eastern European Basin* extends from the Barents Sea to the Caspian Sea and covers an area of 1.5×10^6 km^2.
CIS. Potash deposits are known in several parts of the western foothills of the Urals from the Pechora Depression to the Orenburg District, and in the region of the Caspian Depression. The most important reserve is in the area of Solikamsk and Berezniki on the upper Kama, 200 km north of the town of Perm. It has been mined since the late 1920s. Potash seams occur in the upper part of a salt series >400 m thick that is part of the Kungurian. These seams are sylvinitic below and sylvinitic – carnallitic above, interlayered with rock salt. The lower section, consisting of four sylvinite seams of total average thickness 20 m, with a K_2O content of 15 – 20 %, is mined at a depth of 300 – 500 m in predominantly level deposits [4, 27, 37].

3) *The Midcontinental Basin of North America* stretches from North Dakota to Texas but is broken up into numerous smaller basins. Horizons of rock salt are present in almost the whole of the Permian system. The deposition of potash in large quantities apparently took place only during a small part of the Upper Permian period in a subregion of the Delaware basin of New Mexico and Texas [27].
United States. In Carlsbad, New Mexico, sylvinite and langbeinite are mined in the 50 –140-m-thick McNutt potash zone of the Salado formation in five out of a total of eleven potash seams up to 3 m thick in a level deposit at a depth of 250 – 575 m. The sylvinite contains 12 – 30 % K_2O, and the langbeinite 7 – 9 % K_2O. Massive and disseminated polyhalite, carnallite, kieserite, kainite, leonite, glauberite, and thenardite are also present [4, 27, 37].

4) *Brazil.* In the Amazon basin at Nova Olinda, 150 km south of Manaus, drilling of a level deposit of Lower Permian sylvinite at a depth of 1000 – 1150 m has been carried out. The thickness is up to 4.5 m, and the K_2O content 17 %. Extractable reserves amount to ca. 35×10^6 t of K_2O [4, 37].

Jurassic. *Turkmenistan/Uzbekistan.* Up to six seams of sylvinite can be found at a depth of 200 – 1200 m in the Gaurdak formation in the areas of Gaurdak – Tyubegatan, Kugitang, and Okuzbulak; and carnallite may be found at Karlyuk. The seams of sylvinite, up to 6 m thick, contain 12.5 – 25 % K_2O, sometimes with as much as 12 % insoluble material. A deposit at Karshi in Uzbekistan is to be exploited, and solution mining on a pilot scale has been started at Karlyuk [4, 37].

Cretaceous. Along the east coast of Brazil and the west coast of Africa from Gabon to Angola, Lower Cretaceous potash-bearing evaporites occur. Their similar formations indicate the existence of a common sedimentation area before the two southern continents began to drift apart during the tectonic movements of the Cretaceous period [4, 37].

Brazil, Sergipe. The Taquari-Vassouras deposit of the Muribeca formation has been mined since 1985. It has a basal layer of tachhydrite, above which is a thin layer of carnallitite and two seams of sylvinite, 10 m and 8 m thick, containing 15 % K_2O, with a rock salt bed 4 – 10 m thick between the two seams. The reserves of sylvinite amount to 525×10^6 t, with $16\,000 \times 10^6$ t of carnallitite [4, 37].

Congo. Salt deposits have been formed in ten sedimentation cycles, of which the second highest contains four sylvinite seams. The other cycles contain large masses of carnallitite, and, as in Sergipe, tachhydrite. Mining of the sylvinite in the third layer (depth of 370 m, 3 – 16 % K_2O) began in 1969 but ceased in 1976 when the mine became flooded in the space of two days [4, 37].

Thailand. The lower part of the Maha-Sarakham formation below the Khorat Plateau northeast of Bangkok consists of evaporites with a potash sequence up to 90 m overall thickness at depths of 90 – 530 m. The K_2O content of the carnallitite, which can be 15 m thick, is usually ca. 10 %, but can occasionally reach 14 %. Sylvinite, with a maximum thickness of 3.7 m and a K_2O content of 18 %, has been found in only a few of the 48 exploration boreholes, with tach-

hydrite in some locations. Test mining has begun in the concession areas, which cover 300 km^2 [4, 37].

Tertiary. *France.* The Lower Oligocene deposit in Alsace contains two sylvinite seams in a marl – rock salt series. The upper layer has a thickness of up to 2 m and contains 19 – 25 % K_2O; the lower, up to 5.5-m-thick layer, with 15 – 23 % K_2O, also contains 15 % insolubles (clay, anhydrite, and dolomite). Mining is carried out at comparatively high rock temperatures at a depth of 500 – 1000 m in flat or slightly inclined seams that have been disturbed by faults [4, 37].

Spain. Deposits are located in two areas of the Ebro basin. In Catalonia and Navarra, potash salts lie above rock salt. These deposits are up to 10 m thick in Catalonia and up to 15 m in Navarra. Above this occurs an interbedded deposit of rock salt, carnallitite, marl, and anhydrite. Only the sylvinite seams A and B are mined. These are up to 4 m in total thickness at a depth of 1020 m, some deposits being level and some inclined. The crude salt contains 12.5 – 14 % K_2O [4, 37].

Italy. The Miocene evaporites starts with an anhydrite – polyhalite – halite series followed by rock salt with up to six kainite interbeds and a roof of kieserite – sylvinite. Since 1976, only the kainite seams, which are up to 32 m thick, and contain 12 – 14 % K_2O, have been mined at ca. 800-m depth in seams inclined at 25 – 65° [4, 37].

CIS. In the eastern Galician foredeep of Carpathia, potash salts have been known since 1804 (mainly langbeinite and kainite, with a little sylvinite) and have been mined since 1864 at Stebnik and Kalusch. The individual lenticular deposits occur in five horizons of 1 – 5 m thickness, the kainite containing 10 – 12 % K_2O and the sylvinite 8 – 19 %. The deposit is inclined at 45° [4].

Pleistocene. In the Danakil depression, Ethiopia, is a salt basin of ca. 40 × 100 km, 100 m below the surface. Boreholes have revealed a potash zone containing sylvinite, carnallitite, and kainite at a depth of ca. 740 m [4].

Salt Lakes and Subterranean Brines. *Israel and Jordan.* Potassium chloride, magnesium chloride, rock salt, soda, chlorine, and bromine are obtained from the Dead Sea [4, 37].

United States. Potassium and sodium sulfate are extracted from the Great Salt Lake [4, 37]. Potassium and magnesium chloride are obtained from subterranean brines from the Great Salt Lake Desert [4]. Potassium chloride and sulfate, sodium borate, and boric acid are obtained from subterranean brines in Searles Lake [4, 37].

Australia. Langbeinite is obtained from subterranean brines at Lake McLeod.

China. Tsaerhan Lake, a dry lake, ca. 1100 km northeast of Lhasa, the largest salt lake in the Chaidamu basin, appears to be the most important potential reserve of potassium chloride in China [4, 37].

3. Mining of Potash Salts

3.1. Shaft Mining

Mineral salts are very soluble, and therefore any flow of water into the mine from the overlying strata, which are normally water bearing, must be prevented. This causes difficulties when sinking a shaft, and severe accidents have been caused by influxes of water. The freezing technique, especially deep freezing, is comparatively safe and is used to sink most mineshafts. The shaft itself is protected from water-bearing rocks by the use of tubbings, which are segments bolted together to form rings and are usually made from cast iron or steel-reinforced concrete. The shafts generally have a diameter of 5 – 7 m, and the depth can exceed 1000 m.

3.2. Extraction, Conveying, and Haulage

In most potash mines, the salt is mined from subhorizontal deposits. Generally, rooms are created by removing the salt, and pillars are left between these to prevent the cover rocks from collapsing. This enables an extraction rate of 25 – 60 % to be achieved. For cost reasons the mined-out rooms are not backfilled. In some mines, the total ore is extracted, which causes substantial subsidence of the overlying strata (Alsace).

In steeply dipping deposits (e.g., in the salt domes of northern Germany), roof mining was

originally carried out. This was later replaced by floor mining and then by funnel mining, which is now being used increasingly in numerous variations [43]. Entry drifts are driven one above the other at intervals of 15 – 20 m, and the remaining potash salt is mined by sublevel stoping. Material loosened by explosives falls via the lowest funnel-shaped region into the main haulage level underneath. The mined-out room, 100 – 250 m in height, is usually backfilled with salt waste after mining. Funnel mining is much safer and cheaper than roof mining, because both ore stoping and backfilling take place under gravity, and the mined room need not be reentered. During drilling of the blast holes, the miners are protected by horizontal pillars between the sublevels.

Drilling and blasting operations are carried out with the help of trackless vehicles. Large holes with a diameter of ca. 40 cm and a length of 7 m are drilled by mobile drilling equipment, and another mobile drilling rig is used to drill blast holes around the larger hole in a predetermined pattern. The explosive (generally ammonium nitrate with addition of oil) is brought to the workplace in tanks carried by diesel vehicles and is blown into the shot holes by compressed air.

In predominantly horizontal sylvinite deposits, the most frequent method of extraction is by cutting with heavy machinery (180 t per unit) at high cutting rates. These machines produce material suitable for transport by conveyor belt, enabling continuous extraction in 30 – 60-m sections.

Extraction by borers with two to four rotors is mainly used to produce long pillars in a room and pillar system (Canada), the length of the chambers being as much as 1000 m. In longwall mining, however, which is usually carried out as a caving operation, two or three drum shearers are used (e.g., in Alsace and the CIS). These machines enable daily outputs between 1500 and 4000 t to be achieved.

The recovered material is transported by trackless diesel or cable-fed electric front-end loaders with a capacity of 15 t. Transport along underground roads is increasingly by conveyor belts but also by electric or diesel trains with 30-t-capacity wagons or by dumper trucks with a hopper capacity of 40 t. For transportation by conveyor belt, the material must first be broken into suitably sized pieces.

The network of roadways for conveying, traveling, and ventilation usually extends >100 km in large potash works. A radio communication system is generally used.

Since the introduction of very heavy machinery and diesel-powered vehicles, extra attention must be given to ventilation. Powerful fans supply fresh air at up to 30 000 m^3/min.

In hoisting shafts, the skips have a capacity of up to 25 t. These operate automatically and supply large intermediate storage bins in the filling station, so that the continuously operating manufacturing plants can be supplied with ore at a steady rate. Average daily throughput can be ca. 30 000 t of ore.

Improvements in mining methods and the introduction of new techniques have enabled the output per worker underground to be increased considerably. In Germany during 1965 – 1974 the output of potash ore increased by 20 %, despite a >50 % reduction in the number of employees.

3.3. Solution Mining

Solution mining is an alternative to conventional mining for the extraction of potash ore. The advantages of this method are that the high expense of sinking a shaft is eliminated and reserves can be exploited where conventional mining is impossible (e.g., at great depth). Also, this method can be used where existing mine workings are available but conventional mining methods are no longer feasible, even though extensive reserves may still exist.

Since 1964, Kalium Chemicals in Saskatchewan has operated a plant in which brine extracted from a potash deposit at a depth of ca. 1500 m is used to produce very pure potassium chloride. The process is based on a series of patents [44], but details have not yet been published. Water or an unsaturated solution of potassium chloride is passed through a system of boreholes into the potash seam, which is 20 –25 m thick; potassium chloride and sodium chloride are dissolved. The almost saturated solution is pumped to the surface and fed to the production plant. Rock salt above the potash seam is protected from dissolution by an oil

or air cushion (see Fig. 1). The brine produced passes through multiple-effect evaporators in which sodium chloride crystallizes. Potassium chloride is then crystallized in a series of vacuum coolers [45].

Figure 1. Solution mining
a) Overlying rock; b) Oil cushion; c) Partly unsaturated salt solution; d) Saturated salt solution; e) Cavity produced by dissolution; f) Potash deposit; g) Sodium chloride layer

In Utah (United States), where it was necessary to terminate a conventional mining operation due to severe geological and technological problems, operation was resumed in 1972 by using solution mining. Shafts and underground cavities were flooded, providing a route for the brine formed when water was fed in to dissolve the salt. The brine was passed into surface ponds where solar evaporation caused a mixture of potassium chloride and sodium chloride to crystallize, which was treated in a flotation plant to produce 60 % K_2O potassium chloride [46].

In Canada a conventional mining operation was also converted to the solution mining method after penetration of water led to complete flooding of the mine and forced operations to cease. Water is passed via boreholes into the flooded mine and is converted into a concentrated brine, which is withdrawn and cooled in a pond during the very cold Canadian winter. The potassium chloride that crystallizes is recovered and processed to give a salable product [47].

In the former German Democratic Republic, extensive research into the solution mining of carnallite or potassium chloride from carnallitic deposits has been carried out. An experimental plant with a KCl capacity of ca. 50 000 t/a was operated for a long period (see Section 5.2.3) [48].

4. Treatment of Potash Ores

4.1. Intergrowth and Degree of Liberation [49, 50]

The salt minerals in potash ores are intergrown to varying extents. Before the minerals can be separated and the useful components recovered, the ore must be sufficiently reduced in size so that individual components are accessible to the processing method to be used. In the hot leaching process, sylvite is extracted, and therefore it must first be liberated (i.e., it must not be occluded inside other minerals). To achieve this, it is sufficient to break down the ore to a particle size of 4 – 5 mm or less.

Figure 2. Thin sections of sylvinite ores
A) Coarsely intergrown (potash works in Lanigan, Canada); B) Finely intergrown (Kaliwerk Sigmundshall, Germany)

For the mechanical treatment processes (i.e., flotation, electrostatic treatment, and gravity separation), liberation of the minerals must be complete (i.e., individual grains must consist as much as possible of pure minerals). The extent to which the minerals in the potash ore are intergrown can vary greatly from deposit to deposit (see Fig. 2), which means that the crude salt must be size-reduced to varying degrees before further processing.

The degree of intergrowth of individual minerals can be determined by examination of a thin section. A photomicrograph shows the sizes and shapes of individual minerals in relation to each other [51]. The disadvantage of this method is that a thin section gives only a two-dimensional view of a relatively small region of the salt mineral, and a very small sample of the substance is examined. The three-dimensional arrangement of minerals present and their distribution are not observed. For these reasons, and also because of the high cost of preparing thin sections, this method is now of only minor importance for the industrial processing of potash ores.

More usually, the degree of liberation in size-reduced samples is determined. The degree of liberation of a mineral means the percentage ratio of fully liberated mineral particles to the total content of the mineral in the sample.

Degree of liberation:

$$\frac{\%\,\text{Free mineral}}{\%\,\text{Free} + \%\,\text{Intergrown mineral}} \cdot 100$$

The degree of liberation L depends not only on the grain size achieved by the grinding operation but also on the type of grinding. It can be given for particular ranges of grain size so that the way in which it depends on grain size can be determined, or it can be expressed as an average for the total sample (the integral degree of liberation $\bar{L}$). The arithmetic mean of the degree of liberation of each range of grain sizes is obtained from the following formula:

$$\bar{L} = \frac{\sum_{i=1}^{n} L_i p_i a_i}{100a}$$

where p_i is the mass fraction of the ith size range in percent; a_i the percentage of useful mineral in the ith size range; and a the percentage of useful mineral in the total sample. Apart from the fraction of useful mineral a, which is determined by chemical analysis, the liberated, nonintergrown fraction of useful mineral in each grain size range must be determined. Two methods for doing this are possible:

1) Visual estimation (by counting under the microscope) of the proportion of intergrown particles
2) Heavy-medium separation of the free or almost free grains

The first method is easy to apply to salt minerals because the intergrowth effects are readily recognized owing to the transparency of the grains. For coarse-grained materials such as those usually found in ground products from coarsely intergrown potash ores, this process cannot be used.

The separation of free or nearly free mineral grains from a size fraction is carried out by using heavy liquids of appropriate density, such as tetrabromoethane – toluene mixtures. A float–sink separation is carried out to determine the fraction of free mineral grains. This method cannot be used for salt particles with a grain size <0.5 mm because of the agglomeration of fine grains. In this case, the method of counting under the microscope must be used, or the degrees of liberation of the coarser size ranges must be extrapolated.

Figure 3. Liberation curves of sylvinite ores
a) Coarsely intergrown sylvinite ore (from New Brunswick, Canada); b) Finely intergrown sylvinite ore (from a north German salt deposit)

The results are expressed in liberation curves, which give the degree of liberation as a function of grain size (Fig. 3).

4.2. Grinding [52,53]

Potash salts are easily size-reduced. Therefore, fines may be formed, which can cause problems in later stages of processing. Great care must be taken in selection of the equipment for various stages of grinding.

Figure 4. Two-stage grinding system
a) Conveyor belt; b) Grid; c) First screening stage; d) First grinding stage; e) Second screening stage; f) Second grinding stage; g) Bucket elevator

The maximum grain size to which the potash ore is ground depends on the processing method used and the degree of intergrowth of the ore. For the hot leaching process, an upper grain size limit of 4 – 5 mm is adequate. For mechanical processing, the ore must be ground to a degree of liberation > 75 %. For German sylvinite ores and hard salts, this is achieved by grinding to a maximum grain size of 0.8 – 1.0 mm. For the much coarser sylvinite ores of New Mexico, a maximum grain size limit of 2.4 mm is sufficient. The sylvinite ores of Saskatchewan are even more coarsely intergrown, so that size reduction to < 9 mm would give adequate liberation. However, such large crystals cannot be treated by conventional flotation, and the material is therefore normally ground to < 2.3 mm. One large Canadian manufacturer produces a coarse crystalline product by grinding the potash ore to < 9 mm, removing grains < 1.7 mm, and treating this fine material by conventional flotation. The remaining fraction (1.7 – 9 mm) is treated in a heavy-medium separation plant (see Section 5.5), giving a product with 60 % K_2O (95 % KCl) and a size distribution of the granular commercial grade.

Figure 5. Wet grinding and screening of coarsely intergrown potash ore for flotation [5]
Reprinted with permission of the Society for Mining, Metallurgy, and Exploration, Inc.

The preliminary size reduction of potash ore is carried out by underground mobile crushers, usually in the vicinity of a mining operation. When the ore is mined by continuous mining this gives sufficient size reduction for it to go directly to the haulage line. Further size reduction to the grain size required for processing is carried out in two stages on the surface. An initial size reduction with impact or hammer mills (→ Size Reduction, Chap. 3.4.1.) is always carried out to produce 4 – 12-mm particles, depending on the raw material and processing method

to be used. A coarse grinding plant usually includes two grinding and screening stages (see Fig. 4).

The final fine grinding stage is carried out either by wet grinding in rod mills or by dry grinding with rollers or impact crushers (Figs. 5 and 6). Wet grinding with rod mills in a recirculating system with classification is standard for most flotation plants. Classification is by spiral classifiers, vibrating screens, curved screens, or cyclones. Wet screening produces only a small amount of fines and has the further advantage of providing a scrubbing effect that facilitates the removal of clay from clay-bearing ores; a necessary step before the flotation process.

Figure 6. Dry grinding and screening of coarsely intergrown potash ore for flotation [5]
Reprinted with permission of the Society for Mining, Metallurgy, and Exploration, Inc.

The production of a fine product by dry grinding is rarely used in flotation plants. It is indispensable as a preparation for electrostatic processing, which is not compatible either with the changes to the mineral surfaces caused by aqueous solutions or with excess moisture. The grinding operation must be carried out carefully to give a product low in fines. Roller mills and impact mills can be used. Roller mills have the disadvantage that throughputs are relatively low and maintenance costs are high. Although this was the preferred method in the early days of electrostatic processing owing to its gentle grinding action, it has now been largely replaced by impact grinding, which is also used for size reduction of the middle product from electrostatic separation [54].

5. Potassium Chloride

Potassium chloride [*7447-40-7*], KCl, mineral name sylvite [*14336-88-0*], forms colorless nonhygroscopic crystals. It occurs in many salt deposits (see Section 2.2) mixed with halite and other salt minerals. Natural sylvite is usually opalescent or milky white, as are crystals obtained from an aqueous solution. Sylvite is often colored red by hematite. With magnesium chloride it forms the double salt carnallite [*1318-27-0*], $KCl \cdot MgCl_2 \cdot 6\,H_2O$, which is also commonly found in salt deposits. Potassium chloride is produced in large quantities from mined potash ores and from salt-containing surface waters. More than 90 % of the potassium chloride produced is used in single- or multi-nutrient fertilizers, either directly or after conversion to potassium sulfate (→ Fertilizers, Chap. 3.). The remainder has various industrial uses and is the raw material for the manufacture of potassium and its compounds.

5.1. Properties

Potassium chloride crystallizes in the cubic system, usually as actual cubes. Some physical properties described are as follows:

Relative molecular mass	74.55
Melting point	771 °C
Crystal system and type	cubic 0_h^5
Refractive index n_D^{20}	1.4903
Density	1.987 g/cm^3
Specific heat c_p	693.7 J kg^{-1} K^{-1}
Heat of fusion	337.7 kJ/kg
Enthalpy of formation ΔH^0	− 436.7 kJ/mol
Entropy S^0	82.55 J mol^{-1} K^{-1}
Dielectric constant (at 10^6 Hz)	4.68
Thermal coefficient of expansion (15 – 25 °C)	33.7×10^{-6} K^{-1}

Solubilities in water at various temperatures appear in Table 5, and the phase diagram of the system $KCl-H_2O$ is shown in Figure 7.

Table 5. Solubility of potassium chloride in water (g/100 g) [16]

Temperature, °C	0	10	20	30	40	50
Solubility	28.1	31.2	34.2	37.2	40.2	43.1
Temperature, °C	60	70	80	90	100	
Solubility	45.9	48.6	51.3	53.8	56.2	

Figure 7. Solubility curves for potassium chloride in water
E = cryohydric point : Ice – potassium chloride solution

In the system $KCl-H_2O$, the only solid phases formed are KCl and ice. The cryohydric point (ice + KCl) is $-10.7\,°C$ (29.7 mol K_2Cl_2/1000 mol H_2O). The boiling point of the saturated solution at 1.013 bar is 108.6 °C (71.6 mol K_2Cl_2/1000 mol H_2O).

5.2. Production by Crystallization from Solution

5.2.1. Phase Theory

The salt deposits were formed by the evaporation of seawater, which contains the principal ions Na^+, K^+, Mg^{2+}, Ca^{2+}, Cl^-, and SO_4^{2-}. With water, these ions constitute a six-component system. The concentration of Ca^{2+} in the most interesting region of the system is negligibly small, so that the system reduces to quinary. It is nevertheless very complicated with, 23 different salts being formed between 0 and 100 °C, depending on the temperature and the ratio of concentrations of the components.

Understanding how the salt deposits were formed and how they behave in dissolution processes requires knowledge of the solution equilibria.

The theoretical foundations for this were laid by VAN'T HOFF et al., who between 1896 and 1906 investigated the formation of oceanic salt deposits [55]. Many investigators have continued this work up to the present.

J. D'ANS critically evaluated all published data up to 1933, expressing his results in graphical form [56]. In the same book, he described experimental methods for determining solution equilibria and gave recommendations for the graphical representation of experimental results [57].

Much of the equilibrium data published up to 1967 are given in [58, 59].

In the years following World War II, in the Kaliforschungs-Institut (Potash Research Institute) of Hanover, AUTENRIETH carried out comprehensive and detailed research into the stable and metastable equilibria of most relevance to potash production (especially from hard salt), giving the results in a form suitable for practical application [60–66].

The intensive investigations carried out into the quinary system make it the most thoroughly investigated system with more than four components. However, only parts of the system that are of most relevance to potash production have been thoroughly investigated. An obstacle in the application of equilibrium data to practical problems is that such a complex system is very difficult to represent in a two-dimensional diagram. However, by fixing parameters, working with projections on a plane, and using diagrams showing lines of constant parameters, even nonexperts can work with them.

The best-known region is that in which the solutions are saturated with sodium chloride. This is also the most important region for potassium chloride manufacture, both by the hot leaching process and by flotation, because in both cases a solution saturated with sodium chloride is used. The most important part of the so-called NaCl saturation space at 25 °C is shown in Figure 8 as a three-dimensional view.

Each point in the interior of this space corresponds to a solution saturated with NaCl, in which the concentrations of $MgCl_2$, K_2Cl_2, and

$MgSO_4$ are given by the distance of the point from the axes. For practical reasons, the concentration figures are given in moles per 1000 mol of H_2O, and the concentrations of KCl and NaCl are given in double moles. If one or more of the salt concentrations increase, and if the saturation concentration of another salt is exceeded, this salt separates out. Its identity depends on the concentration ratio in the solution. Such two-salt solutions (saturated with two salts) lie on two-salt surfaces, which form the boundaries of the saturation space. Of the twelve other salts whose saturation spaces form the boundary of the NaCl saturation space, seven can be seen on the figure because their two-salt surfaces lie in the concentration range of Figure 8.

Figure 8. Three-dimensional view of the quinary system (saturated with NaCl) at 25 °C with 0 – 65 mol $MgCl_2$/1000 mol H_2O, showing stable and metastable regions

The KCl – NaCl two-salt surface on the front side of Figure 8 is of special significance for the potash industry, because it allows solutions to be made up that are saturated with both salts at 25 °C. Such solutions are important in the treatment of sylvinitic potash ores.

In many instances, a salt does not crystallize spontaneously when its concentration exceeds that indicated on a two-salt surface. Instead, highly supersaturated solutions are formed, which can remain stable for hours or days, depending on temperature and composition. These supersaturated solutions are termed metastable. They become stable saturated solutions by crystallization of a salt. In Figure 8, continuations of the stable schoenite – NaCl two-salt surface to the right and left into the unstable region are shown as broken lines. In potash manufacture, stable solution equilibria are seldom attained. This is particularly true for hard salt processing in which NaCl-saturated solutions with high $MgSO_4$ content often lead to the undesired crystallization of double sulfates such as schoenite, leonite, langbeinite, and glaserite. Here, the rates of dissolution, nucleation, and crystallization of these salts as a function of temperature and composition of the solutions are especially important [64–66].

Figure 9. 25 °C isotherms of the quinary system saturated with NaCl
Stable (—) and metastable (– – –) surfaces saturated with KCl and NaCl. Concentrations of K_2Cl_2 (—) and Na_2Cl_2 (– – –) are indicated by lines of equal concentration

For practical application of equilibrium data, the boundary surface of the NaCl saturation space is projected, for example, in the direction of the K_2Cl_2 axis in the $MgSO_4 - MgCl_2$ plane. In Figure 9, the two-salt surface NaCl – KCl for the stable and metastable 25 °C isotherm is shown. The indicated K_2Cl_2 and Na_2Cl_2 lines of constant concentration enable the complete composition to be read off for each of the solutions shown here. By using this diagram, the dissolution and crystallization processes possible in this part of the quinary system can be described quantitatively. To control the crystallization of

potassium chloride from 90 °C solutions in an industrial plant, for example, the most important boundary surfaces of the 90 °C isotherm of the system (Fig. 10) are additionally required.

Figure 10. 90 °C isotherms of the quinary system saturated with NaCl
Stable (—-) and metastable (– – –) surfaces saturated with KCl and NaCl. Concentrations of K_2Cl_2 (—-) and Na_2Cl_2 (– – –) are indicated by lines of equal concentration

If any of the components of the quinary system are present in such small quantities that they have a negligible effect on the process, the mathematical treatment can be simplified by dealing only with the remaining subsystem. The following subsystems are of importance:

1) Na^+, K^+, Mg^{2+}, Cl^-, and H_2O with NaCl saturation (see Fig. 17) for the conversion of carnallite into potassium chloride and bischofite
2) K^+, Mg^{2+}, Cl^-, and H_2O (see Fig. 16) for the decomposition of carnallite
3) Na^+, K^+, Cl^-, and H_2O [57] for the selective dissolution of NaCl (e.g., from crystalline product obtained from hard salt in the hot leaching process)
4) K^+, Mg^{2+}, Cl^-, SO_4^{2-}, and H_2O [61] for the production of potassium sulfate and potash–magnesia
5) Na^+, Mg^+, Cl^-, SO_4^{2-}, and H_2O [57] for the production of thenardite or Glauber's salt

5.2.2. Hot Leaching Process

The hot leaching process is the oldest industrial process used to produce potassium chloride from potash ore. It was first used in 1860 in Stassfurt and since then has been developed further in Germany, where it is still the dominant process. It is especially suitable for treating very finely intergrown ores or ores that contain other salt minerals or insoluble minerals in addition to the sylvite and halite. It enables a high-purity product with a uniform grain size to be produced. In many plants, especially in Canada, where flotation is the main production process, small hot leaching plants are also operated, in which the product fines (<0.2 mm) are recrystallized, or potassium chloride is extracted and crystallized from the flotation residues or thickened clay slurries. These procedures give a considerable improvement in total yield and result in a very pure, completely water-soluble product.

Two different processes are used, depending on the composition of the ore. In the *sylvinite* hot leaching process, the other salts present in addition to KCl and NaCl play only a minor role in the process solutions. In *hard salt* leaching, process solutions contain appreciable amounts of $MgCl_2$ and $MgSO_4$. In the case of carnallite-containing hard salts, preliminary carnallite decomposition must be carried out (see Section 5.2.3.) if the amount of carnallite present exceeds a critical level.

The different solubility properties of sodium chloride and potassium chloride are shown in Figure 11. The solubility of potassium chloride is lower in hard salt solutions than in sylvinite solutions. The difference between the potassium chloride contents of saturated solutions at low and high temperatures is less for solutions of hard salt than for solutions of sylvinite, so that the amount of potassium chloride that can be crystallized from a given amount of solution is smaller, which has a marked effect on the energy requirement. Furthermore, an important difference between the two solution types is that the solubility of sodium chloride in sylvinite solutions decreases with increasing temperature, whereas it increases in hard salt solutions. This is apparent in Figure 11B, which shows the behavior of process solutions in a carnallitic hard salt plant with a magnesium chloride content of ca. 240 g/L. This dependence of the solubility of sodium chloride on temperature and magnesium salt content explains why the sodium chloride

contents of crystallized products differ, depending on whether they came from the treatment of sylvinite or hard salt.

Figure 11. Solubility curves for KCl and NaCl (schematic) A) Sylvinite leaching (with nonevaporative cooling); B) Hard salt leaching

The Process (Fig. 12). The potash ore, ground to a fineness of <4 – 5 mm, is stirred in a continuous dissolver with leaching brine heated to just below its boiling point. The leaching brine is the mother liquor from the crystallization stage of a previous cycle of the process. The quantity of leaching brine required is determined by the amount of potassium chloride in the ore. The potassium chloride should be extracted from the ore as completely as possible, and the resulting product solution should be as nearly saturated as possible. The residue consists of two fractions of different particle size. The coarse fraction is removed from the dissolver and debrined. The fine fraction (fine residue or slime) is removed from the dissolver along with the crude solution, which is clarified with the aid of clarifying agents. The slime that separates is filtered off, and the filtrate from the coarse and fine residues is recycled to the recirculating brine. The residues are washed with water or plant brines low in potassium chloride to remove the adhering crude solution, which has a high potassium chloride content. The residues are then disposed of by dumping (see Section 5.8).

The hot, clarified, crude solution is cooled by evaporation in vacuum equipment. Potassium chloride and sodium chloride crystallize as the water is removed. The sodium chloride content of the crystals formed can be controlled by complete or partial replacement of the evaporated water during crystallization. The crystals formed are separated from the mother liquor and processed further. The mother liquor is heated and recycled to the dissolver as leaching brine.

Figure 12. Overall schematic of a hot leaching process

The leaching process is usually carried out in two stages in a main dissolver and a secondary dissolver. The ground ore is first added to the main dissolver where it is mixed with the already partially saturated solution from the secondary dissolver. This causes the solution to be almost completely saturated, and it is then removed from the leaching equipment. The partly extracted ore is next fed to the secondary dissolver where it comes in contact with fresh leaching brine, and the potassium chloride that was not extracted in the main dissolver is taken up by the solution, which is then fed to the main dissolver. The leaching process in the main dissolver can be cocurrent or countercurrent (Fig. 13).

The residence time in the leaching equipment is insufficient to give complete KCl – NaCl equilibrium. The crude solution always contains less potassium chloride and more sodium chloride than corresponds to equilibrium. Another reason for the potassium chloride concentration to be maintained below saturation is that complete recovery of potassium chloride from the ore is

Figure 13. Schematic arrangements of a hot leaching apparatus
A) Cocurrent flow; B) Countercurrent flow

possible only if the hot solution at the end of the leaching process still has a small capacity for dissolving potassium chloride. Also, the crude solution cools by 1 – 2 °C as it travels from the main dissolver to the overflow from the following hot clarification stage. If the solution leaving the main dissolver were completely saturated in potassium chloride, the potassium chloride would begin to crystallize at this point, leading to losses in the slime.

For the crystallization process the potassium chloride content should be maintained as near to saturation as possible in the leaching equipment, so that the concentration difference between the mother liquor and the hot crude solution is as great as possible. The greater this difference, the smaller is the amount of solution used, and the lower is the energy consumption.

Also, a high concentration of potassium chloride in the solution leads to a high potassium chloride content in the crystalline product obtained on cooling. If the solution is unsaturated with respect to potassium chloride, a corresponding amount of sodium chloride in excess of its saturation concentration is taken up by the solution to compensate for the missing potassium chloride. This means that, on cooling, a quantity of sodium chloride crystallizes, causing a decrease in the potassium chloride content of the product even in sylvinitic solutions in which the solubility of sodium chloride increases with decreasing temperature.

Cooling the crude solution by evaporation increases the concentration of salts present below saturation, and the salts with which the solution is saturated crystallize. Unwanted crystallization of sodium chloride can be prevented by adding water to the vacuum cooling equipment, especially in the case of solutions from sylvinite ore leaching. If the required potassium chloride content in the crystalline product cannot be obtained by adding water to the solution, which is often the case when hard salt is being processed, the same result can be obtained by treating the product with cold water. A product containing 60 % K_2O (95 % KCl) is usually required. By this cold-water treatment technique, it is even possible to obtain a product with 62 % K_2O (98 % KCl). The spent solution is recycled to the process.

For KCl of analytical or pharmaceutical quality, potassium chloride produced by the hot leaching process must be purified by single or multiple recrystallization.

Processing of Hard Salt. Unlike the sylvinitic potash ores, whose principal constituents are sodium and potassium chloride, hard salts contain not only the alkali chlorides but also large amounts of kieserite, usually with

varying amounts of carnallite, langbeinite, and anhydrite. Therefore, process brines produced by the leaching of hard salt are characterized by high contents of magnesium chloride and magnesium sulfate, which make potassium chloride production more difficult.

Magnesium sulfate comes mainly from kieserite, which is very soluble (Fig. 14) but has a slow rate of dissolution that becomes even slower if large amounts of dissolved $MgCl_2$ are present. The amount of magnesium sulfate that dissolves depends on the grain size of the ore fed to the dissolving equipment, the kieserite content of the ore, the time for which the crude salt – solution mixture is stirred, the temperature, and the magnesium chloride content of the brine.

Figure 14. Metastable solubility of kieserite in the quinary system saturated with KCl and NaCl between 75 and 110 °C, and solubilities of langbeinite and glaserite at 90 and 100 °C

Magnesium chloride results from reaction of dissolved magnesium sulfate with potassium chloride to give sulfate-containing double salts, and also from any carnallite ($KCl \cdot MgCl_2 \cdot 6\,H_2O$) present in the hard salt. In general, the $MgCl_2$ and $MgSO_4$ contents are kept constant in the circulating brines, so that the rate at which magnesium is taken up from the ore is balanced by the rate at which it leaves the system in the residues and products. If the ore contains large amounts of carnallite, part of the circulating brine must be removed continuously from the system to prevent the $MgCl_2$ level becoming too high.

Because of the large amounts of magnesium salts in process brines, the hard salt leaching process has three important disadvantages compared with the sylvinite process:

1) In solutions of hard salt, the range of solubilities is considerably less than in solutions of sylvinite (Fig. 11). To extract a given amount of potassium chloride, much more liquor, and hence more energy, is required compared with sylvinite.
2) With solutions of hard salt, crystallization of double sulfates such as schoenite, leonite, and langbeinite often occurs. These salts can appear in the residue or the product, which leads either to potassium losses in the residue or to a lower K_2O content of the product. Also, double salts can crystallize in pipelines, vessels, and pumps, interfering with the process and in extreme cases bringing it to a standstill. The particular double salt that crystallizes depends on the $MgCl_2$ content of the solutions, the temperature, and other operating conditions (Figs. 9 and 10). The extent of supersaturation with double sulfates must therefore be controlled to prevent uncontrolled crystallization of double salts and consequent introduction of impurities into the product or disturbance of the process. To achieve this, the circulating brine, or part of it, is fed to a reactor in which it is agitated intensively in the presence of nuclei (20 – 40 wt %) of the double salt to be removed until the brine is no longer supersaturated with respect to it [67].
3) Another disadvantage of the hard salt leaching process is that, with higher magnesium salt contents, the temperature dependence of the solubility of NaCl becomes unfavorable (Fig. 11), that is, when the potassium chloride is crystallized by cooling, considerable amounts of sodium chloride can also crystallize (Fig. 15). In practice, equilibrium is not completely reached when the KCl – NaCl is dissolved, and cooling of the solution often occurs by water removal, so that the K_2O content of the crystals formed is usually only a little more than 40 %. Since the usual potassium chloride for fertilizers (excluding special products) has a minimum potash content of 60 % K_2O, this primary product was formerly crystallized in a second leaching plant. Alternatively, a product can be made with 60 % K_2O directly, if the crystallization of sodium chloride during vacuum cooling is prevented by addition of sufficient water before or during crystallization of the solution

to ensure that only potassium chloride crystallizes [67]. The K_2O content in the product of a primary crystallization can be increased to the required level by treating the product with water or a plant solution unsaturated with respect to sodium chloride. Both the excess water added during vacuum cooling and the water used for treating the product must be removed from the recirculating system of the plant. Both cause a loss of yield whose extent depends on operating conditions. To avoid this, excess water must be evaporated from process liquors.

Figure 15. K_2O content of the crystalline product obtained by cooling an equilibrium solution saturated with NaCl and KCl from 90 to 25 °C without evaporation while maintaining saturation

5.2.3. Processing of Carnallite

Carnallite, $KCl \cdot MgCl_2 \cdot 6\,H_2O$, is the most abundant potassium mineral in salt deposits and occurs widely in mixtures with halite or with halite and kieserite in the form of carnallitite ore (see Section 2.2). In the early days of the potash industry in Germany, it was the preferred starting material for the production of potassium chloride. Today, sylvinitic ores and hard salts are used almost exclusively, because the extraction and processing of carnallite ore are considerably more difficult and expensive for the following reasons:

1) Carnallitite ore has unfavorable mechanical properties that make mining more difficult.
2) The K_2O content of pure carnallite is ca. 17 %, compared with ca. 63 % for pure sylvite.
3) Whereas the separation and purification of sylvite from sylvinite ore can usually be carried out by flotation, which does not involve a phase change, the extraction of potassium chloride from carnallitite ore necessitates dissolution or decomposition of the carnallite, and a high energy consumption for decomposition or purification of the decomposition product, depending on the process.
4) The treatment of carnallite generates large quantities of concentrated magnesium chloride solution, which must be disposed of.

For these reasons, mined carnallitite ore is today seldom used as a raw material. However, carnallite is often a major component in mixed salts of the hard salt type, and hence influences the choice of processing method.

Large quantities of a carnallite – halite mixture obtained by solar evaporation of water from the Dead Sea are used for the production of potassium chloride in Israel and Jordan.

Theoretical Basis. The theory of the production of potassium chloride from carnallite and carnallite-containing mixed salts is based on the $K_2Cl_2 - MgCl_2 - H_2O$ system shown in Figure 16, which is valid between − 3 and 117 °C. In VAN'T HOFF coordinates (moles of salt per 1000 mol H_2O) the points representing the composition of water ($P^{O}_{H^2}$), bischofite ($P_{bischofite}$), and carnallite ($P_{carnallite}$) are indicated. All possible mixtures of water and carnallite are shown on the straight line between $P^{O}_{H^2}$ and $P_{carnallite}$, the molar ratio $K_2Cl_2 : MgCl_2$ here being always 1 : 2, as in carnallite. The curve from L_4 via R and E to point L_0 represents an arbitrary isotherm, and indicates compositions in which solutions are in equilibrium with the corresponding solid phase. Point L_0 gives the solubility of KCl in water, and the solutions L_1 are in equilibrium with KCl as the solid phase. Solution E is in equilibrium with the solid phases KCl and carnallite, and the solutions L_2 are in equilibrium with carnallite only. Solution R is in equilibrium with bischofite and carnallite. The solutions L_3 are in equilibrium with bischofite, and point L_4 indicates the solubility of bischofite in water.

Figure 16. The system $K_2Cl_2 - MgCl_2 - H_2O$ (not to scale) represented by using van't Hoff coordinates

If carnallite is dissolved in water, the composition of the solution follows the straight line $P_{H_2O} - P_{carnallite}$, which intersects curve L_1 at point D. Here, the solution is saturated with KCl, and further addition of carnallite results in dissolution of $MgCl_2$ and crystallization of KCl until point E is reached. This incongruent solubility is the basis for the simple method of processing carnallite (i.e., cold decomposition by mother liquor).

Table 6. Composition of stable saturated solutions in Figure ∗

Point	Temperature, °C	Density, g/cm^3	Concentration, mol/1000 mol H_2O			
			K_2Cl_2	$MgCl_2$	$MgSO_4$	Na_2Cl_2

∗ Solutions Q_2^5 and Q_1^{05} are saturated with $MgSO_4$ and NaCl, and correspond to solutions E_2^5 and E_1^{05}, which are saturated with NaCl.

Carnallitic potash ores or crystallized products from solar evaporation always contain so much halite that solutions produced during processing are saturated with sodium chloride. Figure 17 is a section from the quaternary system $K_2Cl_2 - NaCl - MgCl_2 - H_2O$ saturated with NaCl, showing the 25 °C and 105 °C isotherms. The kieserite content in the ore in the region of the solutions E has in practice a negligible effect on the composition of the solutions. Some analyses of equilibrium solutions of the quaternary system are given in Table 6.

Processing Methods. Many processes for the treatment of carnallite have been described in the literature and used [10], but only a few are important today. By far the most important is cold decomposition by mother liquor. The complete dissolution process is still used occasionally.

Cold decomposition is carried out at ambient temperature (e.g., 25 °C). Carnallitite ore is mixed and agitated with water or with a solution of low $MgCl_2$ content such that the composition of the mixture corresponds to point B in Figure 17. This causes the crystallization of an amount of potassium chloride corresponding to the line $B - E_{25}$, with formation of a solution of composition E_{25}. The very fine potassium chloride produced still contains fine, salted-out sodium chloride, undissolved halite, and sometimes kieserite and clay, depending on the composition of the carnallitite ore used. Approximately 85 % of the potassium chloride contained in carnallite can be obtained as a crystalline product by this process. The yield can be increased by evaporative concentration of the decomposition mother liquor E_{25} or Q_{25} (analyses are given in Table 7). During evaporation, sodium chloride and sometimes magnesium sulfate crystallize and must be removed. The synthetic carnallite that crystallizes when the concentrated solution is cooled is fed to the cold decomposition process.

Potassium chloride from the decomposition, which consists of very finely divided particles and is rather impure, must be purified. Purification by flotation is difficult owing to the fineness of the decomposition product (see, however, Section 5.3.6). For this reason, purification is nearly always carried out by the hot leaching process, which yields a very pure, completely water-soluble, coarse-grained product.

The mother liquor E_{25} or Q_{25} from the decomposition process can take up a certain amount of sodium chloride (see Table 7). If the carnallitite used in the cold decomposition contains only small amounts of halite and if water is used for the decomposition, potassium chloride can be produced that requires no further purification, because sodium chloride has dissolved

in the decomposition liquor. In Israel, a large proportion of the carnallite – halite mixture recovered from the Dead Sea by solar evaporation is so completely freed from halite by fractional crystallization and hydraulic classification that a grade of potassium chloride with > 60 % K_2O can be produced directly by cold decomposition. This so-called cold crystallization process is carried out so that the crystals produced have the same grain size as those from the crystallization plant of the hot leaching process and no further increase in grain size is required. A schematic diagram showing various processes used in the treatment of carnallite from the Dead Sea is given in Figure 18.

Figure 17. Quaternary system (K_2Cl_2 – $MgCl_2$ – Na_2Cl_2 – H_2O) saturated with NaCl
See text for explanation

In the electrostatic treatment of carnallitic hard salts (see Section 5.4.2), concentrates can be produced that contain various amounts of halite together with sylvite and carnallite. These concentrates are reacted with suitable process brines or with water to bring about cold decomposition of the carnallite. The K_2O content of the product, and hence its potential use, depend on the halite content of the concentrate.

The complete dissolution process is used in an experimental plant in central Germany in which carnallite is extracted from a salt deposit by solution mining (see Section 3.3) [48].

The crude salt is dissolved by a solution in which the magnesium chloride content is adjusted so that at the chosen temperature of ca. 80 °C, no decomposition of carnallite takes place, and hence no crystallization of potassium chloride, and the carnallite is completely dissolved. The solution, which is almost saturated with carnallite, is pumped out, evaporated, and cooled, causing crystallization of the carnallite, which is then treated by the cold decomposition process to produce potassium chloride.

For mixed salts containing less than ca. 15 % carnallite, carnallite decomposition is generally dispersed with, and the ore is treated directly by the hot leaching process. The magnesium chloride that enters the process in the carnallite must be removed from the brine circuit in appropriate process brines. If the carnallite content of the ore is high, a carnallite decomposition stage is carried out before the hot leaching process.

5.2.4. Equipment

Leaching. The choice of leaching equipment depends on the properties of the material to be leached and the throughput required. The techniques used in plants in which the potash is completely leached (e.g., in many German and French plants) differ fundamentally from those in plants (e.g., in Canada) where only the fine materials from a screening operation, cyclone fines, and slimes are recrystallized or extracted.

Potash ores are leached at rates of up to 1000 t/h salt, producing up to 2000 m^3/h solution. Screw dissolvers, up to 14 m long and 3 m in diameter, are widely used (Fig. 19). High material transfer is achieved by fitting partitions in the upper part of the dissolver at intervals of 2 – 3 m. These are immersed in the suspension of crystals and force the solution to flow perpendicular to the main flow direction. At the outlet of the dissolver, the solids are scooped from the solid – liquid mixture by an elevator system with perforated buckets from which liquid drains during conveying; the residual water content is ca. 15 – 20 %. Alternatively, bucket wheels can be used.

Elevators or bucket wheels remove only the coarse residue (ca. 75 % of the total residue)

Figure 18. Flow diagram for potassium chloride production by the Dead Sea Works Ltd. (Israel) [4]
Reproduced from [4] with permission

from the screw dissolver. The amount of potassium chloride-containing solution adhering to the coarse residue is usually lowered to 2 – 4 % by centrifugation.

The fine residue (ca. 25 % of the total residue), which consists of very fine salt and insoluble components of the ore (mostly anhydrite and clay), flows with the raw solution from the screw dissolver into the hot clarifier, where flocculation agents are added and sedimentation occurs. Sealed, insulated circular clarifiers are used. The fine residue is removed from the hot

clarifier as a suspension with a solids content of ca. 50 % and debrined on rotary filters to a residual water content of 10 – 16 %. To avoid losses of potassium chloride, the solution adhering to the residue must be removed. For small quantities of residue, this is done by washing on the filter with water or a process brine having a low potassium chloride content. For large amounts of residue, two- or three-stage water washing is used; the filter cake is slurried with the water, and the resulting suspension is filtered. This treatment is repeated once or twice.

In North America, where the flotation process predominates and only small quantities of ore are treated by the hot leaching process, a series of agitated vessels is used. The leaching process takes place in either cocurrent or countercurrent flow. Between the stages of countercurrent leaching, solid – liquid separation is carried out with hydrocyclones or hydroclassifiers [68]. The layout of a leaching plant including crystallization is shown in Figure 20.

Crystallization [69, 70]. The hot solution from the clarifier of the leaching plant is almost saturated with potassium chloride and is cooled by expansion evaporation in vacuum equipment to cause crystallization. The vapors are condensed in surface or barometric condensers, with process brines used for higher temperatures and cooling water for lower temperatures. The amount of heat that can be recovered depends on the number of stages in the cooling system. In the past, vacuum cooling plants were constructed with up to 24 stages, to give maximum possible heat recovery. However, the number of stages in a modern plant is usually between four and eight.

The high cooling rate of a vacuum plant results in a high degree of supersaturation that produces very fine crystals, unless the design of the plant and the crystallizing conditions are optimized to give a coarse product. Several suitable crystallizers are now available (→ Crystallization and Precipitation).

If it is not important to have coarse crystals (e.g., if they are to be reprocessed), stirred crystallizers or conical-based evaporators are used. The former consist of horizontal cylindrical vessels divided into chambers by vertical walls. The solution or suspension flows from chamber to chamber through openings in the walls as it is cooled. These crystallizers are provided with mechanical stirrers or air agitation (Fig. 21).

The conical-based evaporator consists of a vertical cylinder with a lower conical section. The solution is sprayed into the top, and much of the water evaporates. A certain liquid level is maintained in the evaporator, into which liquid from the nozzle falls as a supersaturated solution. Several evaporators are arranged in series one above the other so that the suspension flows through each stage in the direction of decreasing pressure without the need for intermediate pumps (Fig. 22). The advantage of this arrangement lies in its very simple and economical construction, with no moving parts. However, the product is very finely divided.

The aim of the crystallization process is usually a dust-free product with optimum grain size. Two main requirements must be met to achieve this: the solution must have only a slight degree

of supersaturation, and this should be removed by crystallization on seed crystals that are already present. The slight degree of supersaturation is achieved by providing internal circulation within each crystallization stage, in which the cooled solution is mixed with the added hot solution in an exactly controlled ratio. The continuous presence of seed crystals is ensured by keeping the solids content in each crystallizer at ca. 30 wt %.

Figure 23. Oslo crystallizer

These conditions are fulfilled by two types of crystallizer: the fluidized-bed (Oslo) type and the draft-tube agitated type.

In the Oslo crystallizer (Fig. 23), the solution is supersaturated in a separate evaporator and flows into a crystal slurry vessel below, where the supersaturation is removed by crystallization on KCl crystals already present. To reduce the degree of supersaturation in the evaporator, a large amount of clarified solution is pumped from the crystal slurry vessel into the evaporator, together with the incoming hot feed solution. Clarified solution for the next stage is removed from the vessel at another takeoff point. A crystal suspension is also removed from the vessel at a rate corresponding to the rate of crystallization, and is fed either to the next stage as seed crystals or to the debrining stage. Crystallizers of this type are constructed by companies such as Lurgi, Swenson, and Struther-Wells.

In draft-tube agitated crystallizers, a state of supersaturation is created and removed in the same crystallizer. This type is manufactured by Swenson (DTB=draft tube baffle), Standard-Messo, and Kali und Salz. In the Swenson (→ Crystallization and Precipitation) and Standard-Messo (→ Crystallization and Precipitation) crystallizers, the entire suspension is brought into continuous contact with the evaporator surface by a propeller stirrer that provides internal circulation; immediately after supersat-

uration is achieved, a large quantity of salt is made available to remove the state of supersaturation. The coarser crystals collect preferentially in the lower part of the crystallizer, where they are removed as a suspension and fed to the next stage or to the debrining stage. The hot solution is passed through a clarifying zone and is fed to the next stage.

All the processes described so far are operated cocurrently (i.e., the crystallizing salt is transported with the cooling solution from one stage to the next). In contrast, the Kali und Salz process (Fig. 24) operates countercurrently [71]. The salt produced in each crystallizer is passed through a classifier at the bottom of the crystallizer as soon as a predetermined minimum crystal size has been reached; then, unlike the other systems, it is passed to the next hottest stage. The classifier is fitted with equipment that enables the upward flow rate, and hence crystal concentration and product crystal size, to be controlled independently of the throughput rate of the solution. Mixing of the cooler solution with the hotter solution in a crystallizer is prevented by transferring the salt with the help of the solution from the stage into which it is pumped.

5.3. Flotation

Since the early 1900s, ores of many different kinds have been processed by froth flotation. A general description of this process is given in → Flotation.

Investigations into the flotation of potash ores began in the early 1930s in the United States and the Soviet Union [72,73]. The first full-scale plant began production in 1935 in Carlsbad (New Mexico, United States) [74].

The first reports of investigations into the flotation of potassium salts in Germany appeared in 1939 [75]; the first full-scale plant began operating in 1953 [76,77].

At present, most of the worldwide production of potash fertilizers is by flotation. This is the most widely used process in Canada, the United States, the CIS, and France. Small hot leaching plants are often attached to the flotation plants for treating slimes and intermediate products. The flotation process is not widely used in Germany, where a combination of electrostatic treatment with the hot leaching process predominates.

5.3.1. Potash Ores Suitable for Flotation

Various types of crude potash salts can be treated by flotation:

Sylvinite ores are mixtures of sylvite (KCl) and halite (NaCl) in varying ratios. They represent the majority of potash ores treated. The sylvinites of Canada, the United States, and the CIS also contain up to 8 % clay components [78].

Hard salts contain kieserite ($MgSO_4 \cdot H_2O$), as well as sylvite and halite, and sometimes also anhydrite ($CaSO_4$).

Mixed salts consist of a mixture of sylvinite ore or hard salt with carnallite ($KCl \cdot MgCl_2 \cdot 6\,H_2O$).

Polymineral salts contain not only sylvite, halite, and kieserite, but also langbeinite ($K_2SO_4 \cdot 2\,MgSO_4$), kainite ($4\,KCl \cdot 4\,MgSO_4 \cdot 11\,H_2O$), polyhalite ($K_2SO_4 \cdot MgSO_4 \cdot 2\,CaSO_4 \cdot 2\,H_2O$), and clay.

5.3.2. Carrier Solutions

In the flotation of water-soluble salts the carrier liquids are salt solutions that are saturated with the components of the raw material.

Thus, sylvinite ore flotation is carried out in a KCl – NaCl solution. For the flotation of hard salt, the brine also contains various amounts of magnesium sulfate and magnesium chloride.

5.3.3. Flotation Agents

The *collectors* are the true flotation agents, which selectively coat the surface of the component to be floated. For the flotation of sylvite, straight-chain primary aliphatic amines are used in the form of their hydrochlorides or acetates [79]. Mixtures of amines of various chain lengths,which largely eliminate the effects of pulp temperature variation, are extremely useful. A typical flotation amine has, for example,

Figure 24. Kali und Salz countercurrent crystallization process
a) Crystallizers; b) Bells; c) Draft tubes; d) Liquor overflow; e) Stirrers; f) Condenser; g) Thickener; h) Centrifuge; i) Dryer; j) Combustion chamber

the following composition: 5 %$C_{14}-NH_3Cl$, 30 %$C_{16}-NH_3Cl$, 65 % $C_{18}-NH_3Cl$, iodine number: 4.

Foamers contribute to the dispersion of long-chain amines and to the stabilization and homogeneous distribution of amine micelles [80]. The following substances are preferred: aliphatic alcohols with chain lengths $>C_4$, terpene alcohols, alkylpolyglycol ethers, and methyl isobutyl carbinol, which is used mainly in Canada and the United States.

Extenders for sylvite flotation are nonpolar materials, especially oils of various types. They are probably incorporated in the micelles and increase their hydrophobic properties. Extenders are especially effective in the flotation of coarse particles [81].

Clay depressants are used in salt flotation to block clay components, which would otherwise bind large amounts of flotation agent. Clay contents of 1.5 – 2 % can be controlled by treatment with these depressants. If larger amounts are present, additional steps must be taken (clay flotation or classification). Clay depressants include guar and starch products, carboxymethyl cellulose, and polyacrylamide [78].

5.3.4. Theory

The combinations of reagents used for sylvite flotation have been found by empirical investigation.

Theoretical studies of the separation of potassium and sodium chloride by flotation have led to various interpretations.

The theories developed up to 1961 are thoroughly discussed in [82], which also describes experimental results that have contributed greatly to the understanding of salt flotation.

The most important theories are reviewed below:

According to the *exchange theory* [83–85], hydrophobic properties can be imparted to a mineral if the polar group of a collector can be incorporated into the crystal lattice in place of an ion. In the flotation of sylvinite ore, for example, exchange between the K^+ ion (radius: 0.135 nm) and the NH_3^+ group of the amine (radius: 0.143 nm) is assumed to occur, whereas the Na^+ ion (radius: 0.095 nm) is too small (Fig. 25). This does not account for the fact that kieserite ($MgSO_4 \cdot H_2O$), for example, is readily floated by amines in water although the Mg^{2+} ion has a radius of only 0.065 nm.

Figure 25. Incorporation of a polar group of the collector into the crystal lattice [83]
Reprinted with permission of the Society for Mining, Metallurgy, and Exploration, Inc.

The *structure theory* [86] postulates that the interanion distance in the crystal lattice of the salt matches the intermolecular distance in the lattice of the amine hydrochloride within ± 20 %. In sylvite, this condition for oriented growth of the collector on the crystal is fulfilled (Fig. 26), whereas the interionic distance of 0.398 nm in the halite lattice is too small. However, langbeinite has good flotation properties, although these steric requirements are not met [86].

Figure 26. Lattice analogy between the amine and the salt [86] (distances in nm)

According to the *hydration theory* [87], flotation of a mineral is impossible if it has a positive heat of solution, whereas salts with negative heats of solution can be flotated. If heat is evolved when a salt dissolves, more energy is produced by hydration of the ions than is required for breakdown of the lattice. This suggests that such salts are strongly bonded to water molecules, preventing adhesion of the collector. A comment on this theory is given in [88].

Another hydration theory is based on new information on the hydration of ions in dilute solutions [89]. This differentiates between positive local hydration (in which the ion reduces the mobility of the neighboring water molecules) and negative local hydration (water molecules close to the ions are more mobile than in pure water).

According to [90], in the case of positive local hydration (e.g., with Na^+ ions), the Cl^- ions are shielded by water molecules, so that the bond between a cationic amine and sodium chloride can only be weak. In the case of negative local hydration (e.g., with K^+ ions), formation of a bond with the collector is unhindered. Application of these theories, developed for dilute electrolyte solutions, to the hydration state of salt surfaces is difficult, but should be qualitatively valid [90].

The G zone theory (G = Grenzflächen = interfaces) [91] applies both to the flotation of sylvinite with amines and to the flotation of kieserite with an anionic surfactant (the sodium salt of a highly sulfated fatty acid). In both cases, adsorption of the collector proceeds by the same mechanism.

Figure 27. Flotation of potassium chloride with octylamine in saturated solutions of KCl and KCl + NaCl (Feed material: 20 % KCl, 80 % NaCl; 0.1 – 0.315 mm)
a) Carrier liquid saturated in KCl and NaCl (low solubility of octylamine); b) Carrier liquid saturated only in KCl (high solubility of octylamine)

Amines and the anionic surfactant, in a saturated solution of salts that can be floated with these reagents, are present either as micelles or in true solution. In the usual carrier brines,

flocculation (amines) or formation of very small droplets occurs (anionic surfactant).

Based on experimental results, zones are assumed to be formed on the surfaces of crystals suspended in a mixed-salt solution (carrier liquid) in which ions from the lattice are present in the form of a saturated solution.

When collectors are introduced into the suspension, they migrate to the zones where their solubility is greatest due to their thermodynamic tendency to dissolve (i.e., to the boundary zones of those particles that they cause to float). The bonding of the collectors in these zones is reinforced if their solubility in the surrounding carrier brine is low. The success of flotation depends on the strength of this bond (Fig. 27).

Froth cannot be produced in the usual carrier liquids either by collectors or by foaming agents. The collision of an air bubble with a crystal coated with the collector material causes the latter to spread over the surface of the bubble, stabilizing it and causing the crystal to float.

Large-scale operations of sylvite and kieserite flotation has thus been placed on a good unified theoretical foundation.

5.3.5. Flotation Equipment

The flotation equipment used in the potash industry resembles that used for flotation of other ores (→ Flotation, Chap. 5.3.).

Mechanical flotation cells operate with a rotor – stator system that causes both thorough mixing of the pulp and thorough distribution of the air, which can be drawn in by suction or injected from a compressed air network.

In recent decades, high-capacity flotation has been introduced almost everywhere. In this process, several stirrers operate in a single trough [92].

Agitair high-capacity flotation equipment is used in Germany, and the preconcentrate is purified in individual cells of the Denver type. Wemco high-capacity machines are used by the French potash industry, and Mechanobr high-capacity cells by the former Eastern-bloc countries.

Modified Mechanobr M 7 fluidized-bed units (Fig. 28), manufactured by Mescerjakov, are standard equipment in the CIS [93, 94]. Typical features include the presence of a grid and circulation of the suspension via a box on the front wall of the cell, connected to the agitator by a circulation pipe.

Figure 28. Mechanical flotation cell with fluidized bed

Figure 29. Principle of pneumatic free-jet flotation
Reproduced from [95] with permission

Pneumatic flotation equipment operates without stirrers. In the free-jet flotation process developed in Germany [95], the conditioned pulp is pumped through an aerator fitted with a porous gas distributor or annular nozzle, either outside or inside the separation vessel, and flows

as a free jet into the separation vessel. Air bubbles with the adhering minerals rise to the top and form a froth that flows over the edge of the vessel into a channel (Fig. 29). The pneumatic flotation process has been tested successfully for a special case of sylvite flotation. It is used industrially for the recovery of kieserite from leaching residues.

Figure 30. Pneumatic coarse-grain flotation cell (Gogorchimproect type) [96]
a) Feeding device; b) Spray nozzle; c) Aeration system (perforated rubber tubes); d) Device for removing reject material

In the CIS, a pneumatic flotation cell has been developed for the treatment of coarse sylvinite ores with a maximum grain size of 3–5 mm [96, 97] (Fig. 30). The conditioned pulp is fed from above onto a layer of froth immediately above the perforated-tube aeration system. The hydrophobic sylvine crystals are retained in the froth, so that mechanical damage of the bubble–crystal combination is kept to a minimum. The flotation rate is very high.

5.3.6. Processes

Sylvinite Ore Flotation. Pure sylvinite of German origin can be floated without serious problems. The components of the ore are relatively strongly intergrown [50] and must be broken down by grinding until each grain consists as far as possible of only one component.

The ore is first ground to a particle size of < 4 mm, screened to remove fines, and then slurried with carrier brine and ground to a grain size of $< 0.8 - 1.0$ mm in a circulating system that includes rod mills, spiral classifiers, or wet screens (Fig. 31).

The solids content of the flotation pulp is adjusted to 30–40 wt %, and it is then mixed with flotation agents (ca. 40 g of oil, 20 g of foaming agent, and 40–80 g of collector per tonne of crude salt). As much of the desired product as possible is then extracted by the three-stage high-capacity rougher flotation. The rougher tails are classified in hydrocyclones, debrined (the coarse fraction in centrifuges, and the fine fraction in rotary filters), and dumped. Since the filtrate still contains finely divided salt, it is clarified in a thickener and recycled for slurrying the ore.

The material floated in the rougher flotation is then concentrated in a cleaner flotation process, usually in three stages. This does not produce a marketable product (with $> 60\,\%$ K_2O). The concentrate is therefore separated from the brine and washed with water in salt washing equipment.

This washing process dissolves more halite than sylvite, producing a potash salt that meets quality requirements. The washing liquor is removed by centrifuges, and the product is dried and conveyed to silos.

The cleaner flotation process also produces some intermediate-quality product with a fairly high K_2O content, whose coarse particles contain most of the residual intergrown material from the ore. They are therefore recovered by hydrocyclones and fed to the screening–grinding stage for size reduction. The energy consumption for the entire process is ca. 10 kW · h/t ore.

Figure 31. Flow diagram of the flotation of potash ores

The treatment of sylvinite ores from Canada, the United States, and the CIS is more difficult owing to the clay content of up to 8 %. The clay components disintegrate in the brine, forming very fine slimes that absorb large quantities of flotation agent. The flotation process is therefore sometimes preceded by a desliming stage (Fig. 32). The clay is first detached from the surface of the salt by vigorous agitation in scrubbers, so that it can be floated in a separate operation. The clay is usually removed by multistage classification [98]. The fine material is then thickened and washed with water to reduce losses of K_2O. Up to 1.5 – 2 % of residual clay in the crude salt can be handled by adding clay depressants (see Section 5.3.3).

An advantage of clay-bearing sylvinite ores is that they are usually sufficiently liberated at grain sizes of < 3 – 5 mm. Sometimes, coarse crystals are floated separately from fine crystals (→ Flotation, Chap. 5.4.4.→ Flotation, Chap. 5.4.5.).

Hard-salt flotation is similar to the sylvinite flotation process (Fig. 31). However, the flotation product also contains kieserite, which cannot be removed by washing because it dissolves only slowly in water.

Sylvite, which is intergrown with kieserite, must therefore be liberated as fully as possible, which leads to increased grinding costs. Because of the increased production of fines, more flota-tion agent is needed. Also, in warm summer months, potassium-containing double salts (leonite, schoenite) can separate from the circulating brine. Since these salts end up in the residue, the yield is reduced.

Mixed-Salt Flotation. Carnallite ($KCl \cdot MgCl_2 \cdot 6\,H_2O$) in the mixed salt is usually decomposed by a brine with low $MgCl_2$ content. The potassium chloride produced has a grain size of < 0.04 mm and is accompanied by sylvinite ore or hard salt components.

In the 1980s, this complex salt mixture was successfully treated by flotation alone for the first time [99, 100].

Potassium chloride produced by the decomposition is first floated with a fairly small amount of amine in pneumatic or stirred flotation cells; then the sylvite component of the sylvinite ore or hard salt is floated with a further measured amount of amine, and a discardable residue is obtained (Fig. 33). The flotation froth is then treated by flotation in cleaner cells to give a concentrate with > 55 % K_2O. A final washing process gives a potash fertilizer salt containing > 60 % K_2O.

Polymineral salts are rarely treated by flotation. Potash ore from Stebnik (CIS) contains not only sylvite, halite, and clay materials, but also large amounts of kainite, langbeinite, and polyhalite [101]. Clay depressants are added first, followed by flotation of halite with a mixture of $C_7 - C_9$ fatty acids. Sodium hydroxide solution is used to adjust pH [101].

Figure 33. Flotation of fine salt (< 0.1 mm) from carnallite decomposition, showing K_2O content of each size fraction [100]
Yields are based on amounts of K_2O in each fraction

Schoenite can be floated from a salt mixture by using coconut oil acids as the collector [102].

The flotation of anhydrite to produce a salt mixture of kieserite, langbeinite, and polyhalite is recommended in [103].

A combination of cold leaching and flotation for the treatment of salt mixtures containing langbeinite and polyhalite is described in [104].

5.4. Electrostatic Separation

Electrostatic separation depends on the directional movement of electrically charged bodies or particles in an electric field. The processes used differ according to the various methods of producing or separating the charges and according to the separation equipment used (→ Electrostatic Separation). The separation of mixtures of salt minerals (e.g., in the treatment of crude potash ores) invariably involves the selective exchange of electric charges that takes place on contact between the various mineral particles, followed by separation in free-fall separators. Although roll separators are widely used for treating other minerals, they have not been used for salts, mainly because of their low throughput.

The first investigations into the industrial-scale separation of potassium chloride and sodium chloride were carried out after World War II by the International Minerals & Chemical Corp. in Carlsbad, New Mexico [105]. The ore, which contains alkali-metal chlorides and various amounts of clay and sulfate minerals, was ground, heated to ca. 500 °C, cooled to ca. 110 °C, and separated in a free-fall separator with a field strength of 2 – 6 kV/cm. Results were not encouraging and the method was abandoned.

Research in the Kaliforschungs-Institut in Hannover in 1956 led to an industrial breakthrough. The addition of organic and inorganic reagents much improved the electrical charge ex-change between the mineral components, and the separating temperature could be reduced to < 100 °C [106, 107]. The potash works of Neuhof-Ellers, a subsidiary of Kali und Salz, was the first industrial plant to use this process to produce kieserite in 1974. In the following years, plants for the electrostatic production of kieserite and potash concentrates, and for the dry removal of residues, were installed in three other factories, with capacities up to ca. 1000 t/h [108]. Investigations aimed at the introduction of this process for processing sylvinite ores from the potash deposits in Saskatchewan, Canada, have been carried out by PCS Mining, Saskatoon [109].

5.4.1. Theoretical Basis

The basis of the process is the mutual selective exchange of electrical charge between the salt components, which occurs on contact. The direction, selectivity, and intensity of the charge exchange can be influenced by a large number of reagents (conditioning agents) [110]. In addition to this chemical conditioning, treatment with air of specific relative humidity is necessary. This is usually controlled by means of the air temperature and should be between 5 and 25 % [110, 111]. By the appropriate choice of conditioning agent and relative humidity, the charging properties of the individual mineral components in a potash ore can be controlled so that the desired components are recovered. In this way, an ore of complex composition can be completely separated into its components [112].

The mechanism of charging by contact depends on the transfer of electrons between the touching mineral surfaces, which must have suitable surface properties (i.e., surface energies appropriate for the exchange of charge). These energies are influenced (or created) by chemical conditioning agents and partial water vapor pressure [113–115].

5.4.2. Equipment and Processes

Before the separation process, the potash ore must be size-reduced to give complete liberation of its components. Fine particles (< 0.1 mm) behave nonselectively in an electrostatic field, so the grinding process must be carried out as carefully as possible (e.g., by impact grinding). The conditioning agents (20 – 100 g/t ore) are added to the ore in a mixer or introduced in the vapor state into the fluidized-bed dryer that heats the salt to the separation temperature (25 – 80 °C), whereby the relative humidity is adjusted to a suitable value for selective charging of the salt particles [116–118]. Alternatively, a rotary dryer can be used. Depending on the conditioning

agent used and the relative humidity and temperature, sylvite generally becomes positively charged, whereas halite and kieserite can be positive or negative. Accompanying minerals such as langbeinite, carnallite, or kainite can be separated individually or together with other mineral components [119–122].

Figure 34. Vertical belt separator
a) Rotary brush; b) Rubber belt; c) Stationary brush; d) Flaps

Separation of the mixture of charged minerals is carried out in free-fall separators with an electrical field strength of 4 – 5 kV/cm. For a distance between the electrodes of 25 cm, the applied voltage is 100 – 125 kV. Formerly, vertical belt separators (Fig. 34) were common, but they are now used only for special applications. The electrodes consist of rotating rubber belts with conducting coatings. Brushes on the side opposite the electric field remove salt fines, which otherwise settle on the electrode surface, forming a coating that weakens the electric field and hinders separation. The separator used exclusively today is the tube free-fall separator (Fig. 35), which was developed by the potash industry [123]. It consists of two opposed rows of steel tubes, ca. 2 m long. The tubes rotate on their axes, and salt fines are removed by brushes on the side remote from the falling salt. The maximum working length of separators of this type is ca. 10 m. The charged salt mixture leaving the fluidized bed is fed to the top of the separator and falls through the electric field between the electrodes. This causes the particles to move sideways, the direction depending on the sign of the charge. At the bottom of the separator, adjustable flaps enable a cathodic fraction, an anodic fraction, and a middle fraction to be recovered. These fractions are then treated further or removed from the process as product and waste (or middlings).

Figure 35. Tubular free-fall separator
A) Cross section; B) Plan viewa) Salt feed; b) Upper bearing; c) Motor; d) Tubes; e) Brushes; f) Lower bearing; g) Flaps; h) Receiver for products

The particle sizes for complete liberation should not exceed 1.5 –2 mm for sylvite and halite, or 1.2 mm for kieserite, because the movement of particles in the electric field of the separator is determined by both the horizontal

electrical force and the vertical effect of gravity. Since the electrical force depends on the charge on the particle, which in turn is a function of the surface area, the surface – volume ratio is a very important factor in determining the extent of sideways movement in the electric field. For fine materials, the effect of the electrical force is the greater; the converse is true for coarse particles.

Modern tube free-fall separators have a throughput of $20-30\,t\,h^{-1}\,m^{-1}$. Their energy consumption is very low because for this throughput the current is only ca. 2 mA.

Generally, even for a single-stage separation step two free-fall separators are arranged one above the other so that the concentrate and waste material from the upper separator bypass the lower one, while the middlings flow directly to the lower separator where further separation occurs. This is shown schematically in Figure 36. In most cases, multistage separation or treatment is necessary, in which the concentrate produced in the first stage is purified or concentrated in another single stage or in multistage separation (Fig. 37).

Electrostatic separation has thus far been used industrially on a large scale only for the treatment of hard salts with the principal components sylvite, halite, kieserite, and various percentages of carnallite. Three basic methods of separation into the individual components are

1) Separation of sylvite in the first stage [105, 111, 124], and separation of kieserite and halite in the second stage
2) Separation of kieserite in the first stage [125, 126], and separation of sylvite and halite in the second stage
3) Separation of halite in the first stage [127–129], and separation of kieserite and sylvite in the second stage

In all cases, carnallite appears in the sylvite fraction.

The first stage of method 2 is used to produce kieserite on a large scale, and method 3 is used in several variations for the production of a dry halite residue and of kieserite and potash concentrates [108]. So far, these plants have been operated almost entirely in association with leaching and flotation plants because electrostatic treatment alone gives unsatisfactory yields.

5.5. Heavy-Media Separation

Heavy-media separation is not used widely in the potash industry because of the generally unfavorable extent of intergrowth and the small density difference between the main components sylvite ($\varrho = 1.99$) and halite ($\varrho = 2.17$). However, the process can be used for very coarsely intergrown high-quality sylvinite ores as mined in Saskatchewan. International Minerals & Chemical Corporation (IMCC) operates a plant of this type in Esterhazy, Saskatchewan [130]. The heavy medium is a suspension of magnetite in a saturated salt solution whose density is adjusted to 2.10. Small salt crystals (< 1.7 mm) are very difficult to separate from magnetite; therefore, only materials with a particle size of 1.7 – 8 mm are treated by this process. Separation is carried out in hydrocyclones in two stages. A process scheme is given in Figure 38.

IMCC also operates a heavy-media separation plant in Carlsbad, New Mexico, where langbeinite ($\varrho = 2.83$) is recovered from a potash ore in which sylvite and halite are the other main components.

5.6. Debrining and Drying

The products and waste from all the treatment processes except for the dry electrostatic process are obtained as suspensions with various solids contents and must be debrined. The two main aims of debrining potassium chloride product are (1) to achieve as low a moisture content as possible to minimize drying costs and (2) to remove as much of the adhering brine as possible to maximize product purity. As the brine adhering to the residues contains potassium chloride, its recovery minimizes yield losses.

Suspensions must often be thickened in circular thickeners or hydrocyclones before debrining.

The choice of equipment is determined mainly by the particle size of the material to be treated. The extent to which adhering brine can be removed by washing with water is also important.

Figure 37. Flow diagram of electrostatic separation plant

Pan filters are used where debrining of a fine-grained product is combined with water washing to increase the K_2O content and when the product is to be stored intermediately. Residual moisture content in this case is 12 – 14 %.

Drum filters (→ Filtration, Chap. 8.6.) are generally used for debrining fine residues or when washing of the filter cake is necessary; they give a residual moisture content of 9 – 11 %. Alternatively, belt filters (→ Filtration, Chap. 8.2.) are used because they have a high capacity and allow the filter cake to be washed with recovery of the washing liquids.

The most commonly used debrining apparatus consists of centrifuges of various designs (→ Centrifuges, Filtering) [131]. In potash works in Canada, the United States, Jordan, and the CIS, screen-bowl and solid-bowl centrifuges of 1400-mm diameter are in general use. Screen-bowl centrifuges have throughputs

Figure 38. Heavy-media separation of potash ore [130]
Reprinted from [130] with permission of John Wiley & Sons, Inc.

of 60 – 110 t/h and achieve a residual moisture content of 3 – 8 %. They are used to treat both products and residues. Solid-bowl centrifuges mostly are used for fine residues, and achieve throughputs of 70 – 120 t/h and a residual moisture content of 6 – 8 %. In European and some Canadian factories, large-diameter (> 900 mm) pusher centrifuges are used, with throughputs of 40 – 50 t/h and a residual moisture content of 3 – 6 %. For coarse products and residues, vibratory screen and screw screen centrifuges are generally used. These have a diameter of 900 – 1200 mm and a throughput of 35 – 70 t/h, and give a residual moisture content of 2 – 4 %.

The products are usually dried in drum dryers (→ Drying of Solid Materials, Chap. 2.1.2.) with diameters up to 3 m and lengths of 20 m [132]. They are heated with oil or gas in cocurrent flow at throughputs up to 120 t/h. The dryers are fitted with internals to promote heat exchange and prevent caking of the salt. Exhaust gases are dedusted, first by cyclones and then by electrostatic filters, wet scrubbers, or fabric filters. The main reasons for the widespread use of drum dryers are their ruggedness, safe operation, lack of sensitivity to throughput variations, and adaptability to differing grain sizes and moisture content. Figure 39 gives a schematic diagram of a drying plant of this type.

Since the early 1960s, fluidized-bed dryers have been used to an increasing extent (→ Drying of Solid Materials, Chap. 2.1.3.). At first, they were used mainly for coarse products (> 0.5 mm) with low initial moisture content. Later, improvements in fluidized-bed technology enabled products with grain size down to 0.1 mm and initial moisture content up to 8 % to be dried. Their most important advantages compared with drum dryers are improved heat and mass transfer, more efficient use of energy, and much smaller floor space requirement. Cyclones and bag or electrostatic filters are used for dedusting the exhaust gases from a fluidized-bed dryer. A typical plant is shown in Figure 40.

5.7. Process Measurement and Control

The methods normally used in the chemical industry for measuring and controlling process parameters are also used in potash plants. Special methods include the analytical determination of potassium by means of its natural radioactivity [133], the use of flame photometry for so-called ratio analysis, and mineral analysis by infrared spectrometry.

The natural mixture of potassium isotopes includes ca. 0.012 % of the radioactive isotope ^{40}K, which is both a β and a γ emitter. Both types of radiation are measured to determine potassium content. The β emissions are usually measured in the laboratory, whereas on-line measurement of γ emissions is widely used for process control. Owing to the great penetrating power of γ rays, the reliability of measurement is strongly dependent on the geometry of the measuring equipment. Equipment for the radiometric determination of potassium in bulk products is shown in Figure 41 [134].

The on-line method of ratio analysis [135, 136] of KCl – NaCl mixtures is based on measuring the potassium and sodium contents of

a sample with a double-beam flame photometer, and calculating the ratio from the measured data. Since this ratio is independent of the weight and dilution of the sample wet materials with varying water content can be analyzed without weighing the sample. Ratio analysis is used for determining residual NaCl content in flotation concentrates that have been water washed. The NaCl content is used to determine the amount of washing water required, and enables losses of K_2O due to excessive use of washing water to be avoided. The method has also been used for controlling the K_2O content in products from leaching – crystallization plants.

Figure 41. Equipment for radiometric determination of potassium in solid materials
a) Inlet for material to be analyzed; b) Container for material to be analyzed; c) Bypass; d) Detector; e) Time-controlled valve

Infrared spectroscopy is suitable for continuous determination of carnallite or kieserite in crude potash salts. Reflection photometry can be used to measure water of crystallization, and hence the content of these minerals. In some circumstances, the carnallite content can be determined even when kieserite is present [136].

5.8. Waste Disposal and Environmental Aspects [137, 138]

The main environmental problem of the potash industry is disposal of process waste. The total world production of potash ore is ca. 250×10^6 t/a, whose processing necessitates the disposal of ca. 200×10^6 t of waste without damage to the environment [137]. In the Canadian province of Saskatchewan alone, 300×10^6 t of solid waste has been generated during the last 30 years, covering an area of ca. 35 km^2 with solid and liquid materials [139].

The composition of the waste depends on the type of ore treated. Waste from the treatment of sylvinite consists mainly of halite. Waste materials from hard salt treatment are halite and kieserite, and from carnallitite ore processing, halite and magnesium chloride, which is always produced in the form of an aqueous solution. Salt solutions that must be disposed of are also generated during the production of potassium sulfate from potassium chloride and magnesium sulfate, and during the recovery of kieserite from residues from the treatment of hard salt by dissolving the halite (→ Magnesium Compounds, Chap. 5.3.1.).

Four methods for disposing of waste are dumping, backfilling, pumping into the ground, and discharge into natural water systems.

The disposal of waste by dumping is by far the most important method. Salt solutions that run off the dumped materials must be demonstrated not to harm the environment when they are absorbed into the ground. Salt solutions can originate from the brine adhering to wet residues or from the carrier liquid for transporting solid waste to the dump, or they can form when atmospheric precipitation dissolves the salt from waste material. If the ground underneath the dump is not impermeable, it must be sealed by layers of clay or plastic sheeting, or a combination of the two. The salt-containing runoff water is collected in ditches at the edges of the dump, and as much as possible is returned to the recirculating brine system in the plant. Excess brine is disposed of along with other liquid waste. In Germany, solid waste is formed into steep conical heaps after drying or debrining as fully as possible. This reduces the amount of salt-containing runoff water formed by atmospheric precipitation and also minimizes the

ground area required. In most Canadian installations, filtration residues (tails) are slurried with brines and pumped as a suspension into a large lagoon surrounded by dykes. Flat deposits are formed over a very large area. The brine that runs off is pumped back to the plant and reused for slurrying solid waste (Fig. 42) [140, 141]. If the salt solution enters groundwater-bearing layers despite sealing, boreholes are sunk, and salt-bearing groundwater is pumped back into the lagoon. Attempts to cover dumped waste material to prevent the formation of salt-containing water by the leaching effect of rainfall have in the long run proved unsuccessful [139].

Under certain geological conditions, and if mining methods are suitable, solid residues can be transported underground for backfilling. Since the bulk density of the residue is much lower than that of the potash ore, often only a part of the residue can be accommodated by the space left after extraction of the ore. Backfilling is the main method of waste disposal in North German salt works where the salt beds are steeply inclined, as well as the potash works of New Brunswick in Canada. In most potash works, where the potash is mined from level deposits, backfilling is not possible for technical and economic reasons.

Pumping salt solutions back into the ground is possible if certain geological requirements are met. The formation used for this purpose must possess sufficient porosity and permeability, and must have no contact with formations that could provide a water supply or contain salt deposits. Salt solutions are generally pumped under pressure through lined boreholes into the porous formation.

Since 1926, in the Werra potash region of Germany, large quantities of brine have been pumped into a porous dolomite layer 20 – 25 m thick. Injection wells have an absorption capacity up to 1000 m^3/h at head pressures up to 11 bar [142]. Since most of this waste brine comes from kieserite production, the amount produced has decreased drastically with the introduction of electrostatic ore treatment [143]. In Saskatchewan, excess brine is pumped into deep formations of dolomite or sandstone. The capacity of these wells is up to ca. 200 m^3/h at head pressures up to 60 bar. Kalium Chemicals, Saskatchewan, has been disposing of waste brine since 1979 in caverns produced by solution mining.

The possibility of disposing waste brine in rivers and lakes depends very much on the location. Sea disposal, as practiced in the United Kingdom and by one of the potash works in New Brunswick, presents few major problems if the outfall is sufficiently remote from the coast. The potash works on the Dead Sea can dispose of waste brine in the Dead Sea itself without harmful consequences. The Potash Company of America in Saskatchewan discharges its solid and dissolved wastes into the southern end of the salt-containing Lake Patience, which is isolated from the rest of the lake by a dam.

For most potash works, waste brine cannot be disposed in natural salt water. If underground disposal is impossible, disposal into flowing natural water is the only alternative. In all countries, this is subject to ever-stricter regulation. One particular problem, for which a solution in the foreseeable future is being sought, is the high salt content in the Werra River due to brine from the potash works in the eastern part of the Werra region [143].

The only significant atmospheric pollution caused by potash works is salt dust emitted by the drying plant and from the handling of the ore and products during production and supply. Dust removal from waste gases from dryers is discussed in Section 5.6. The dusts produced during production and conveying are usually removed by air extraction, and trapped in fabric filters or wet scrubbers. During the drying of products containing magnesium chloride brines, hydrolysis of the magnesium chloride can lead to the emission of hydrogen chloride, which can be removed from the gas by wet scrubbing or absorption in calcium hydroxide in combination with a woven filter [144]. This procedure can also greatly reduce the level of sulfur dioxide if it is present in the exhaust gas.

5.9. Granulation [145–149]

Potassium chloride can be produced in a wide range of crystal sizes, depending on the composition of the potash ore, its degree of intergrowth, and the process used. Different particle-size distributions are needed for various applications. To meet these requirements, the potash industry

Figure 42. Conventional potash waste handling in Saskatchewan [139]
Reproduced with permission

offers products with standardized size distributions (see Section 5.10) obtained by screening to give the various fractions. The resultant distribution of the product among the various standardized grades does not always correspond to market requirements. Demand for products with a particle size of ca. 1 – 5 mm (coarse and granular grades) exceeds their normal production rate in a potash works. Most potash works must therefore increase the proportion of coarse product by granulating part of the primary product.

The main reason for the high demand for granulated potassium chloride is the technique of applying fertilizers that was developed mainly in North America and Western Europe in the postwar years. This technique, which is now the most widely used, requires coarse particles with a rather narrow size range. This is needed both for single nutrient fertilizers and for bulk-blended materials, which are widely used in North America. Also, granulated potassium chloride has a lower tendency to cake or form dust than the fine product.

Two methods of granulation are commonly used in the fertilizer industry: agglomeration of molten or wet material in rotating drums or dishes, or compaction of dry material in roll presses. The latter is the method most often used for potash fertilizers.

The starting material for compaction usually consists of a mixture of fine material from the production process with recycled material from the grinding and screening system of the compaction plant. Although dusts from the plant can also be compacted, a high proportion of fines (< 0.1 mm) must be avoided because they cause problems in the compaction equipment. Amines from the flotation process on the surfaces of the particles can also interfere with compaction and must be destroyed or rendered inactive by heat or chemical treatment.

Roll presses used in the potash industry usually have 60 – 125-cm-long rolls with diameters of 60 – 100 cm (→ Size Enlargement, Chap. 4.5.3.). The feed material, which is usually at 100 –120 °C, is generally predensified by force feeders that feed it into the nip between rolls, where it is deaerated and compressed, with plastic deformation of each particle, to produce a dense sheet of material. The compression force is 40 – 50 kN/cm of roller length. The sheet of material is fed to a prebreaker that size-reduces it for ease of transportation. It then goes to a grinding – sieving plant, which produces either a granular product or granular

and coarse products. Undersize material is recycled to the compaction press (→ Fertilizers, Chap. 5.3.5.). A typical flow diagram for a compaction – granulation plant is given in Figure 43.

The compaction product consists of irregularly shaped angular particles. Handling causes abrasion of the edges and corners to form unwanted dust. The granular material is therefore usually treated with water after screening and then dried in a fluidized-bed dryer at 180 – 200 °C. This smooths the corners and edges, and gives a dense surface to the granules. Another method of dust reduction is to treat the granules with liquids that bind the dust formed by abrasion (see Section 5.10).

5.10. Quality Specifications

The main application of potassium chloride is in potash fertilizers, either as a single-nutrient fertilizer or as the potash component in mixed or complex fertilizers. In English-speaking areas and on the international market it is often called muriate of potash (MOP).

Single-nutrient fertilizers, which were formerly the most common type, have been replaced largely by complex or mixed fertilizers. Also, the finely divided fertilizers formerly used have increasingly been replaced by granulated products. Single potash fertilizers often contain the additional nutrient magnesium sulfate.

Potassium chloride must have differing grain structure and nutrient content depending on its intended use, e.g., for the production of granulated NPK or PK fertilizers, for application as suspension or liquid fertilizers, for bulk blending with other components (→ Fertilizers, Chap. 3.), or as a single-nutrient fertilizer. The potash industry has developed internationally accepted quality standards.

The three main grades differ in grain size:

Standard	0.2 – 0.8 mm
Coarse	0.8 – 2.0 mm
Granular	1.2 – 3.5 mm

Other products, such as those designated soluble, special standard, or special fine, can contain a high proportion of grains <0.2 mm. Grain-size distributions of the principal grades are listed in Table 7. Products from various manufacturers can diverge considerably from these specifications.

Table 7. Typical grain-size distribution in potash fertilizers (cumulative percentage retained)

Mesh	Tyler	Cumulative subsieve fraction		
width, mm	mesh	Granular	Coarse	Standard
+3.36	+ 6	2 – 12		
+2.38	+ 8	30 – 45	2 – 20	
+1.68	+ 10	75 – 90	25 – 50	
+1.19	+ 14	95 – 98	70 – 90	5 – 15
+0.84	+ 20	99	90 – 98	20 – 45
+0.60	+ 28		99	50 – 75
+0.42	+ 35			70 – 90
+0.30	+ 48			85 – 95
+0.21	+ 65			96 – 98
+0.15	+100			97 – 99

The granular and coarse products are used for bulk blending with other granulated fertilizers or as single-nutrient fertilizers. The standard and other fine materials are used in the manufacture of granulated multinutrient fertilizers, and for suspension and liquid fertilizers.

The potassium chloride content, which for fertilizers is usually given as % K_2O (100 % KCl = 63 % K_2O), is generally at least 60 % K_2O (95 % KCl) for this application. The main impurities include sodium chloride, or magnesium sulfate, and sometimes anhydrite or clay minerals, depending on the raw materials and production method. Fertilizer-quality potassium chloride produced by flotation is often colored red to red-brown by hematite inclusions or salt clay.

For single-nutrient fertilization, especially in European agriculture, potash fertilizers with a low K_2O content are often used. These generally contain a guaranteed level of water-soluble magnesium salts. In Germany, for example, two granulated potash fertilizers with a guaranteed MgO content are widely used: 40er Kornkali with MgO (40 % K_2O, 6 % MgO) and Magnesia-Kainit coarse (11 % K_2O, 5 % MgO, 24 % Na_2O).

About 5 % of the potassium chloride produced worldwide is used as an industrial chemical, mainly for the production of potassium hydroxide (see Chap. 11) and chlorine by chloralkali electrolysis. Material of this quality is produced by recrystallizing low-purity potassium chloride. A distinction is made between industrial-grade and chemical-grade material, depending on the impurity content and area of use. Typical analyses of these products are

Figure 43. Flow sheet of a modern potash compaction – granulation plant [149]
a) Double screens; b) Hammer mills; c) Compactors; d) Screens; e) Fresh feed vessel; f) Recycled materials vessel
Reproduced from [149] with permission

Industrial grade:	KCl:	99.0 – 99.5 %
	NaCl:	0.8 – 0.3 %
Chemical grade:	KCl:	99.8 – 99.9 %
	NaCl:	0.05 – 0.03 %

The remaining impurities consist mainly of bromide and alkaline-earth sulfates, depending on the raw material and production process.

Dust content and free-flowing properties are important quality criteria, and depend on chemical composition and grain size. With granulated materials, dust formation by abrasion occurs due to handling during manufacture and transport even if the materials are specially treated during production (see Section 5.9). To bind the dust, the granulated material is treated with conditioning agents such as polyglycols, mineral oil products, vegetable oils and waxes, or mixtures of these. The addition rates are usually 0.3 – 5.0 kg/t [150, 151]. Various methods have been developed to assess or measure the abrasion resistance and dust content of the granulated product. Abrasion resistance is tested by subject-ing samples of the granules to a process of screening or rolling in a rotating drum with steel spheres or rods, and weighing the fine material formed after a given time [152]. Dust content is determined by air blowing a sample under precisely defined conditions and weighing the dust collected [150].

Fine potassium chloride (standard quality or finer) tends to cake on storage or transport over long distances. Anticaking agents are therefore generally added, usually mixtures of aliphatic amines, or sometimes higher fatty acids. Salt products that do not contain alkaline-earth sulfates are treated with potassium hexacyanoferrate(II). Addition rates for organic anticaking agents are 50 – 300 g/t, but potassium hexacyanoferrate(II) is effective even at 15 – 25 g/t [150, 151]. Anticaking agents can affect the wettability of potassium chloride, which in turn can affect its granulation properties when complex fertilizers are being produced. The anticaking treatment must therefore suit the user's requirements exactly [153].

5.11. Toxicology and Occupational Health

No toxic hazards are associated with the normal handling of potassium chloride. According to USP XVII of 1970, the usual therapeutic dose (e.g., for treating potassium deficiency) taken orally would be 1 – 10 g/d. The LD_{50} (oral, guinea pig) is 2500 mg/kg.

Protective measures for storage and handling and personal protection such as breathing apparatus or gloves are unnecessary.

5.12. Economic Aspects and Uses

A review of world potash production since 1900 is given in Table 8. The figures show the total output from the potash industry including potassium sulfate and potassium products for industrial use [4, 154, 155].

Germany was the sole producer up to World War I, and was later joined by France and the United States, and then Spain, the Soviet Union, and Poland. After World War II, the leading producers were the central and western European countries and the United States. In the 1960s, the Soviet potash industry grew strongly, and the Soviet Union became the leading producer. Also in the 1960s, the first potash works in Saskatchewan was started up. In a few years, several large potash works were in operation there, and Canada became the second largest producer after the Soviet Union. The capital investment in the Soviet Union and Canada and the rapidly increasing use of fertilizers in agriculture in the 1960s and 1970s led to a steep increase in world potash production. Since 1980, the average annual increase in world potash production has been only 0.7 %.

Almost two-thirds of world potash production is exported. All the potash-producing countries are exporters except for Brazil and China. Canada is by far the largest exporter. World exports of potash in 1989 (in 10^3 t K_2O) were as follows [154]:

Canada	6 808
France	517
former East Germany	2 251
West Germany	1 339
Israel	1 007
Italy	64
Jordan	755
Spain	354
United Kingdom	251
United States	482
former USSR	3 407
Total	17 235

The economic situation, particularly in developed countries, greatly influences the extent and regional distribution of exports. Both the quantity exported and its distribution among consumers are greatly affected by the state of their agriculture, especially in developed regions, and by the demand for or availability of convertible currency in the exporting or importing country. Transport costs for potash fertilizers have a considerable bearing on total cost to the consumer, and logistical considerations also influence the direction and size of exports or imports. Finally, fluctuations in the rate of exchange of currencies between the countries concerned are very important.

Because of the conditions described above, certain special regional relationships developed. The agricultural requirements of the former COMECON countries were satisfied by the Soviet and East German potash industries only. In western Europe, the market was supplied almost entirely by western European producers. In North America, Canadian and United States producers were in a dominating position. Canada had a good export market in Asia, as did Europe and Jordan. The Latin American market was supplied mainly by Canadian producers, together with former East Germany and the former Soviet Union. The political and economic changes in the former Eastern Bloc, the unification of Germany, and the collapse of the dollar have all led to changes in the supply–demand relationships described above, although the distance between the producer and the consumer is still of overriding importance. The future development of potash exports will be influenced greatly by imports into China and Brazil. Both countries have only minimal production and are compelled to import fertilizers on a large scale. Problems associated with their internal economies and with foreign exchange have thus far limited imports [156, 157].

The capacities of the potash producers in various countries for 1990–1991 (in 10^3 t K_2O) were [155]:

Middle and Western Europe	8 700
Germany	5 700
France	1 500
Spain	750
Italy	250
United Kingdom	500
North America	13 028
United States	1 838
Canada	11 190
former Soviet Union	12 880
Western Asia	2 220
Israel	1 380
Jordan	840

Estimated world demand for potash fertilizers in the business year 1990 – 1991 by regions (in 1000 t K_2O) was as follows:

Europe	7 520
Eastern Europe	2 120
Western Europe	5 400
former Soviet Union	5 600
America	7 320
North America	5 100
Central America	350
South America	1 870
Asia	4 705
Western Asia	155
Southern Asia	1 360
Eastern Asia	3 190
Africa	522
Oceania	260
World	25 927

In using these figures, it should be borne in mind that the capacities quoted by individual producers are generally too high and that only ca. 95 % of the total potash production is used in the form of fertilizers. Hence, the total consumption of products of the potash industry is ca. 1.5×10^6 t of K_2O higher than the figure given above. Nevertheless, considerable overcapacity exists worldwide, as can be seen by comparing the two tables.

For the use of potassium compounds in fertilizers, see → Fertilizers.

Industrial-grade and chemical-grade potassium chloride are used mainly for the electrolytic production of potassium hydroxide. Other important uses include the production of drilling fluids for the oil industry, aluminum smelting, metal plating, production of various potassium compounds, and applications in the food and pharmaceutical industries [158].

6. Potassium Sulfate [159]

Potassium sulfate [*7778-80-5*], K_2SO_4, mineral name arcanite, forms colorless, nonhygroscopic crystals. It occasionally occurs in nature in the pure state in salt deposits (e.g., in Germany, the United States, and the CIS) but is more widely found in the form of mineral double salts in combination with sulfates of calcium, magnesium, and sodium (see Table 1). Potassium sulfate is, after potassium chloride, the most important potassium-containing fertilizer, being used mainly for special crops. Potassium sulfate constitutes ca. 5 % of the world demand for potash fertilizers.

6.1. Properties

Potassium sulfate forms orthorhombic crystals, which transform to the trigonal modification at 583 °C. Some properties of potassium sulfate are listed below:

M_r	174.25
fp	1069 °C
Crystal system and type	orthorhombic D_{2h}^{16}
Phase change at	583 °C
Crystal system and type at > 583 °C	trigonal D_{3d}^{3}
Refractive indices n_D^{20}	1.4933; 1.4946; 1.4973
Density	2.662 g/cm^3
Specific heat capacity c_p	752.9 J kg^{-1} K^{-1}
Heat of fusion	197.4 kJ/kg^1
Heat of transformation (orthorhombic/trigonal)	48.5 kJ/kg^1
Enthalpy of formation ΔH^0	− 1438 kJ/mol
Entropy S^0	175.6 J mol^{-1} K^{-1}
Dielectric constant (at 4×10^8 Hz)	6.3
Thermal coefficient of expansion (cubic)	130×10^{-6} K^{-1}

Apart from the naturally occurring double-salt minerals mentioned above, potassium sulfate also forms double salts and mixed crystals with ammonium sulfate and the sulfates of beryllium, magnesium, calcium, strontium, barium, and lead. It is reduced to potassium sulfide or potassium polysulfides by reducing agents such as hydrogen and carbon monoxide at high temperature.

The solubility of potassium sulfate in water is listed in Table 9. The cryohydric point is − 1.51 °C (7.1 g K_2SO_4/100 g H_2O), and the boiling point of the saturated solution is 101.4 °C (24.3 g K_2SO_4/100 g H_2O). The solid phases formed in the system $K_2SO_4 - H_2O$ are K_2SO_4, $K_2SO_4 \cdot H_2O$, and ice. In aqueous ammoniacal solution, the solubility decreases rapidly with increasing ammonia concentration [160]. Potassium sulfate is virtually insoluble in industrial organic solvents.

Table 9. Solubility of potassium sulfate in water (g/100 g) [15]

Temperature, °C	0	10	20	30	40	50
Solubility	7.35	9.24	11.1	12.9	14.8	16.6
Temperature, °C	60	70	80	90	100	
Solubility	18.4	20.0	21.5	22.8	24.0	

6.2. Raw Materials

Potassium sulfate is produced from single or mixed minerals or brines, or by the reaction of potassium chloride with sulfuric acid or sulfates [161]. The economically important minerals include the deposits of hard salt in Germany, langbeinite in New Mexico (United States), and kainite in Sicily. In the United States, sulfate-containing crystalline products from the evaporation of water from the Great Salt Lake (Utah) and Searles Lake (California) are also used for the production of potassium sulfate.

Potassium chloride is usually converted to potassium sulfate by reaction with sulfuric acid, but SO_2 – air mixtures can also be used. Reactions with sodium sulfate and gypsum are also of interest. Small amounts of potassium sulfate are obtained during the production of alumina from alunite.

6.3. Production

The choice of production method and the location of a potassium sulfate plant depend on having a plentiful economic supply of the starting materials and being able to utilize or dispose of the byproducts or waste. Most production plants are located on salt deposits from which at least some of the raw materials can be obtained. Plants in which potassium chloride is reacted with sulfuric acid with liberation of hydrogen chloride are usually located in regions with a demand for hydrochloric acid, (e.g., for a acidification of petroleum boreholes), or they operate in conjunction with a chemical works having a process that uses hydrogen chloride. In such cases, the

exploitability of hydrogen chloride determines the capacity of the potassium sulfate plant.

6.3.1. From Potassium Chloride and Sulfuric Acid (Mannheim Process)

The reaction of sulfuric acid with potassium chloride takes place in two stages:

$$KCl + H_2SO_4 \longrightarrow KHSO_4 + HCl$$
$$KCl + KHSO_4 \longrightarrow K_2SO_4 + HCl$$

The first reaction step is exothermic and proceeds at relatively low temperature. The second is endothermic and must be carried out at higher temperature. The relationship between total reaction time and temperature is shown in Figure 44. In practice, the process is operated at 600–700 °C. To minimize the chloride content of the product, a small excess of sulfuric acid is used, which is later neutralized with calcium carbonate or potassium carbonate, depending on the purity requirements for the product.

Figure 44. Temperature dependence of the reaction between potassium chloride and sulfuric acid
Reproduced from [162] with permission

The reaction is usually carried out in so-called Mannheim furnaces (Fig. 45) [162].

The furnace has a closed dish-shaped chamber, with diameter up to 6 m, heated externally by an oil or gas burner. Potassium chloride and sulfuric acid are fed into the chamber in the required ratio at an overhead central point. The mixture reacts with evolution of heat and is mixed by a slowly moving stirrer fitted with stirring arms with scrapers (rabbles), which propels the mixture from the center of the chamber to the periphery. Potassium sulfate leaves the reaction chamber at this point and is neutralized and cooled. It normally contains 50–52 % K_2O and 1.5–2 % chloride. Hydrogen chloride gas formed is absorbed in water to form hydrochloric acid or used in gaseous form.

The Mannheim process is the most widely used method of producing potassium sulfate due to its simplicity, high yield, and the many ways in which the byproduct can be utilized. Hydrogen chloride is used to produce dicalcium phosphate, vinyl chloride, or calcium chloride if it cannot be sold as hydrochloric acid.

Disadvantages of the process include high energy consumption, severe corrosion, and high capital cost. In the United States, reductions in corrosion and energy consumption are achieved by using the Cannon process, in which the reaction is carried out in a directly fired fluidized bed.

Another variation is the Hargreaves process, which is also used in the United States. Briquetted potassium chloride is heated in reaction chambers in a stream of sulfur dioxide from the combustion of sulfur, excess air, and water vapor. The yield and the degree of conversion are both ca. 95 %.

The Mannheim and Hargreaves processes are also used to produce sodium sulfate from sodium chloride and sulfuric acid. Mannheim furnaces can be used to produce potassium and sodium sulfates alternately. Research into the reaction of potassium chloride with sulfuric acid in a liquid–liquid extraction process did not result in the construction of a production plant [163, 164].

6.3.2. From Potassium Chloride and Magnesium Sulfate [165, 166]

In a process used mainly in Germany, the sulfate required is provided by kieserite, $MgSO_4 \cdot H_2O$, a component of German hard salt deposits. Methods of extraction are described in → Magnesium Compounds, Chap. 5. The reaction can be represented by the following overall equation:

$$2\,KCl + MgSO_4 \longrightarrow K_2SO_4 + MgCl_2$$

Kieserite reacts very slowly and must be ground finely before reaction. Alternatively, it can first be recrystallized to give epsomite, $MgSO_4 \cdot 7\,H_2O$.

Figure 45. Schematic diagram of a Mannheim furnace
Reproduced from [162] with permission

The basis of the process is explained in Figure 46. The fundamental relationships for the single-stage process of KUBIERSCHKY and the two-stage process of KOELICHEN and PRZIBYLLA are shown as broken lines on the isotherm diagram.

For the single-stage process, the most favorable mixing ratio of the starting materials is given by point C. In the presence of sufficient water, this mixture reacts to form potassium sulfate and a sulfate mother liquor (point m). This solution has the highest magnesium chloride content attainable by direct reaction, which determines the yield. The magnesium content of solution m reaches a maximum at 25 °C, and the process is therefore carried out at this temperature. The single-stage process achieves a theoretical potassium yield of only 46.1 % and sulfate yield of 67.5 %.

For this reason, the two-stage process is now used exclusively. In this process, the starting materials are first mixed in the presence of a definite quantity of water corresponding to point S to form schoenite, $K_2SO_4 \cdot MgSO_4 \cdot 6\,H_2O$. So-called potash – magnesia liquor, which has a high magnesium chloride content (point P), is also formed. The schoenite is reacted with additional potassium chloride (point D) to form potassium sulfate and sulfate mother liquor:

$$2\,KCl + 2\,MgSO_4 + x\,H_2O \longrightarrow K_2SO_4 \cdot MgSO_4 \cdot 6\,H_2O + MgCl_2\ (aq.)$$

$$2\,KCl + K_2SO_4 \cdot MgSO_4 \cdot 6\,H_2O + x\,H_2O \longrightarrow 2\,K_2SO_4 + MgCl_2\ (aq.)$$

This process gives a theoretical potassium yield of 68 % and sulfate yield of 83.7 %.

The flow diagram of the process is shown schematically in Figure 47.

In the first stage, called the potash – magnesia stage, schoenite or leonite, $K_2SO_4 \cdot MgSO_4 \cdot 4\,H_2O$, is produced by stirring solid epsomite or finely ground kieserite with potassium chloride in sulfate mother liquor recycled from the second stage. The suspension produced is filtered on rotary filters; the potash – magnesia brine, which contains 180 – 200 g/L magnesium chloride, is removed; and the solid crystalline product, also known as potash – magnesia, is fed to the next stage, sometimes after being washed with sulfate mother liquor, where it is stirred with potassium chloride solution at ca. 70 °C. The temperature of the mixture is 35 – 40 °C, and solid potassium sulfate is formed. This is thicknened, debrined by centrifuges, and dried in drum or fluidized-bed dryers.

If the sulfate reaction is carried out in a classifying crystallizer at a high solids content [167], a very pure, coarsely crystalline product is obtained with K_2O content of 53 % and chloride content of < 0.5 %.

In the industrial process, sodium chloride is always present. If the molar ratio of $Na_2 : K_2$ in the sulfate mother liquor exceeds 2 : 5, glaserite, $3\,K_2SO_4 \cdot Na_2SO_4$, is formed instead of potassium sulfate. To prevent this, the potassium chloride used must be of adequate purity.

The yield is determined by losses to the waste brine. The higher the magnesium chloride con-

Figure 46. Isothermals of the system $K_2 - Mg - Cl_2 - SO_4^{2-} - H_2O$ at 25 °C according to JÄNECKE

Figure 47. Flow diagram of the two-stage production of potassium sulfate from potassium chloride and magnesium sulfate

tent of the potash – magnesia brine is, the lower is the potassium content, and therefore the potassium loss. Excess potassium-rich sulfate mother liquor must be recovered.

6.3.3. From Potassium Chloride and Langbeinite [168]

Large deposits of langbeinite, $K_2SO_4 \cdot 2\,MgSO_4$, can be found in New Mexico (United States). Langbeinite can be converted to potassium sulfate according to the following overall equation:

$$K_2SO_4 \cdot 2\,MgSO_4 + 4\,KCl \longrightarrow 3\,K_2SO_4 + 2\,MgCl_2$$

The potash ore also contains halite and varying amounts of sylvite, from which langbeinite is separated by gravity separation, flotation, and dissolution of halite, giving various crystal sizes. The coarser langbeinite fraction is sold as potash – magnesium fertilizer, and the finer fraction is reacted with potassium chloride to pro-

duce potassium sulfate. A flow diagram for the process is given in Figure 48.

Figure 48. Flow diagram of the production of potassium sulfate from langbeinite

The potassium sulfate formed is granulated and marketed in three different grain sizes: granular (0.8 – 3.4 mm), standard (0.2 – 1.6 mm), and special standard. The latter has a high content of grains < 0.2 mm.

6.3.4. From Potassium Chloride and Kainite [161]

In Sicily, kainite, $KCl \cdot MgSO_4 \cdot 2.75\,H_2O$, is obtained from a potash ore by flotation. It is then converted into schoenite at ca. 25 °C by stirring with mother liquor containing the sulfates of potassium and magnesium from the later stages of the process. Schoenite is filtered off and decomposed with water at ca. 48 °C. This causes magnesium sulfate and part of the potassium sulfate to dissolve and most of the potassium sulfate to crystallize. The crystals are filtered and dried. The sulfate mother liquor is recycled to the kainite – schoenite conversion stage. The mother liquor produced there, which still contains ca. 30 % of the potassium used, is treated with gypsum, $CaSO_4 \cdot 2\,H_2O$, causing sparingly soluble syngenite [*13780-13-7*], $K_2SO_4 \cdot CaSO_4 \cdot H_2O$, to precipitate. Syngenite is decomposed with water at ca. 50 °C, which dissolves potassium sulfate and reprecipitates gypsum. The potassium sulfate solution is recycled to the schoenite decomposition stage, and gypsum is reused to precipitate syngenite. A simplified flow diagram of the process is given in Figure 49.

6.3.5. From Potassium Chloride and Sodium Sulfate [164]

The production of potassium sulfate from potassium chloride and sodium sulfate takes place in two stages, with glaserite, $Na_2SO_4 \cdot 3\,K_2SO_4$, as an intermediate, according to the following equations:

$$4\,Na_2SO_4 + 6\,KCl \longrightarrow Na_2SO_4 \cdot 3\,K_2SO_4 + 6\,NaCl$$
$$Na_2SO_4 \cdot 3\,K_2SO_4 + 2\,KCl \longrightarrow 4\,K_2SO_4 + 2\,NaCl$$

Potassium chloride and sodium sulfate are reacted at 20 – 50 °C in water and recycled process brines to form glaserite, which is filtered and then reacted with more potassium chloride and water to form potassium sulfate. Because the mother liquor from the glaserite stage has a high potassium and sulfate content, the maximum potassium yield is 73 %, and the maximum sulfate yield is 78 %. The yield can be increased considerably by cooling the mother liquor to produce more crystals and by including a final evaporation stage.

A production plant in the CIS uses the glaserite process [166], and an experimental plant is operating in Canada [169].

Alternatively, sodium sulfate solution can be used to charge an anion exchanger with sulfate, which reacts with potassium chloride solution to give a high yield of potassium sulfate [170, 171]. This process is used at Quill Lake, Saskatchewan, Canada, which has a high sodium sulfate content.

6.3.6. From Potassium Chloride and Calcium Sulfate

Processes based on gypsum, $CaSO_4 \cdot 2\,H_2O$, have often been proposed, because it is so readily available. Two processes have been tested in experimental plants:

1) Reaction with potassium chloride in strongly ammoniacal solution

Figure 49. Flow diagram of the production of potassium sulfate from kainite

2) Reaction with anion exchangers

Potassium chloride reacts with gypsum in water to give syngenite. If the reaction is carried out in a concentrated solution of ammonia at low temperature, potassium sulfate with a very low syngenite content is obtained [163, 172, 173].

$$CaSO_4 \cdot 2\,H_2O + 2\,KCl \longrightarrow K_2SO_4 + CaCl_2\ (aq.)$$

By carrying out the reaction in two or more stages, high concentrations of calcium chloride in the waste brine can be produced, and hence very high yields. The ammonia required for the reaction medium must be recovered by distillation. This process has attracted some interest [174].

The anion-exchange process is carried out in two stages [175]. First, the ion-exchange resin (R) is treated with a suspension of gypsum, charging it with sulfate. The charged resin is then treated with a concentrated solution of potassium chloride, to replace the dissolved chloride by sulfate. Potassium sulfate crystallizes from the solution, sometimes after the addition of solid potassium chloride. The process takes place according to the following equations:

$$R_2Cl_2 + CaSO_4 \longrightarrow R_2SO_4 + CaCl_2$$

$$R_2SO_4 + 2\,KCl \longrightarrow K_2SO_4 + R_2Cl_2$$

6.3.7. From Alunite [176]

Alunite [*12588-67-9*], $K_2SO_4 \cdot Al_2(SO_4)_3 \cdot 4\,Al(OH)_3$, occurs in several extensive deposits. On being heated to 800 – 1000 °C, it decomposes with liberation of sulfur trioxide to form a mixture of alumina and potassium sulfate. The latter can be extracted from the mixture. A plant in the CIS uses this process.

6.3.8. From Natural Brines and Bitterns

In the United States, large quantities of potassium sulfate are produced from the brines of the Great Salt Lake and smaller amounts from the brines of Searles Lake (see Section 8.3). Extensive investigations and project studies have been carried out in various countries into the extraction of potassium sulfate from the mother liquors (bitterns) produced when salt is extracted from seawater, and from concentrated brines in Tunisia and the Atacama desert of Chile [164].

6.4. Granulation

The demand for granulated potassium sulfate has increased greatly for the same reasons that the demand for potassium chloride has increased. The method of production with compaction rolls is widely used (see Section 5.9), although potassium sulfate does not behave under pressure like potassium chloride, which undergoes plastic deformation with merging of the grain boundaries. However, the granulated product is much more dense and solid if the

potassium sulfate is wetted before compaction by adding up to 2 % water, or if steam is introduced through force feeders located above the compaction rolls. Also, the pressure used must be considerably higher than that for potassium chloride [177, 178]. A compaction plant for potassium sulfate is otherwise similar to that for potassium chloride, although the throughput is much lower.

6.5. Quality Specifications

The important quality specifications for agricultural-grade potassium sulfate, known in the English-speaking world and on the international market as sulfate of potash (abbreviated to SOP), are the K_2O and chloride content. All producers guarantee a minimum K_2O content of 50 % (92.5 % K_2SO_4), typical values being 50.5 –51.0 %. A completely water-soluble potassium sulfate with K_2O content of > 52 % is supplied for the production of liquid fertilizers.

The maximum permissible chloride content is 3 %, according to EC Guidelines, but the usual commercial upper limit is 2.5 %. The chloride content depends very much on the production method, and some producers offer potassium sulfate with chloride content < 0.5 %.

The most common impurities, apart from alkali chlorides, are the sulfates of calcium and magnesium.

The demand for granulated potassium sulfate as a single-nutrient fertilizer and for bulk blending has greatly increased. The crystal size and size distribution of the products granular, coarse, and standard are the same as those for potassium chloride (see Section 5.10).

Potassium sulfate does not cake as readily as potassium chloride and is therefore not treated with anticaking agents. Dust-reducing agents are added at the rate of 5 kg/t to the fine and granulated products; the same additives are used as for potassium chloride (see Section 5.10).

Industrial-grade potassium sulfate with a K_2SO_4 content of 99.6 – 99.9 %, purified by recrystallization, is supplied as a raw material for the production of other potassium compounds and as an auxiliary material or reagent for various branches of industry. Specifications with respect to chemical purity and crystal size distribution are suited to the individual user's requirements and can sometimes be very detailed.

6.6. Toxicology and Occupational Health

No health hazard is associated with potassium sulfate if it is handled in accordance with regulations. According to Swiss law relating to toxic substances, it is a Class 4 material (LD_{50}: 500 – 5000 mg/kg). Otherwise, the information given in Section 5.11 for potassium chloride applies.

6.7. Economic Aspects and Uses

Potassium sulfate accounts for ca. 5 % of world production by the potash industry, expressed in K_2O units. It is produced in 11 countries. Of the total, ca. two-thirds comes from Belgium and Germany. Other European producers are Italy, Spain, Finland, and Sweden. Potassium sulfate is also produced by the CIS. Other production plants are in the United States, Japan, South Korea, Taiwan, the Philippines, and China. Present world production and consumption both exceed 1.5×10^6 t K_2O [179, 180].

A list of the most important exporting countries (exports for 1985 – 1986 in 10^3 t K_2O) is given below:

Western Europe	586
Belgium	256
Finland	18
West Germany	227
Italy	54
Spain	31
former East Germany	61
United States	74
Asia/Middle East	16
Israel	3
South Korea	8
Taiwan	5
Total	737

The consumption (1985 – 1986 in 10^3 t K_2O) amounted to:

Western Europe	558
Eastern Europe	106
Africa	121
North America	115
Latin America	51
Asia/Middle East	271
Oceania	6
Total	1228

Potassium sulfate is up to twice as expensive as potassium chloride based on K_2O content due to the costs of the raw material (potassium chloride) and processing. It is therefore only used as a potash fertilizer for applications where it performs much better than potassium chloride.

The sulfur content of potassium sulfate is an advantage where there is a deficiency of sulfur in the soil. Also, it has only a slight oversalting effect on soil in arid or semiarid areas. It is useful for fertilizing crops that are sensitive to chloride or whose quality is improved by chloride-free fertilization. This applies particularly to tobacco, vegetables, potatoes, vines, and citrus or various other fruit [179, 181].

Potassium sulfate is used in industry for the production of other potassium compounds, accelerators for rapid-setting cements, synthetic rubbers, desensitizers for explosives, lubricants, powdered fire extinguishers, dyes, explosives, and pharmaceuticals.

7. Potash – Magnesia

Crops sensitive to chloride can be fertilized with potassium sulfate alone or by fertilizers containing the sulfates of potassium and magnesium. These consist either of a mixture of the two sulfates or of the double sulfates schoenite, leonite, or langbeinite in dehydrated form.

Formerly, large quantities of a mixture of fine-grained potassium sulfate and kieserite were marketed under the name potash – magnesia (K_2O: 27 – 30 %, MgO: 9 – 12 %). This has since been almost completely replaced by a granulated potash – magnesia fertilizer, which is produced by first mixing potassium sulfate and kieserite at 95 °C with hot synthetic langbeinite. The hot mixture is granulated in a drum granulator, and the product is quickly cooled to < 60 °C. It contains 29 – 30 % K_2O and 10 % MgO.

Langbeinite from the potash deposits in Carlsbad, New Mexico (United States), can be used in the pure state directly as a potash – magnesia fertilizer. Crude langbeinite also contains halite and varying amounts of sylvite, and the method of purification utilizes the low rate of dissolution of langbeinite in water. If the sylvite content is low, the potash ore is first ground to < 6 mm and then simply washed with water to dissolve the halite. The langbeinite that remains is dried and screened to obtain the commercial size gradings. For higher sylvite content, an additional stage is required to separate the components by a combination of gravity separation and flotation. The langbeinite produced has a K_2O content of 20 – 22 % and an MgO content of 18 – 19 %, and is marketed as Sulpomag or K-Mag.

8. Production of Potassium Salts from Other Raw Materials

Potassium salts occur not only in salt deposits, but also in solution in many types of inland lakes and in seawater. Where the concentration of the salt solution is high enough and the climatic and topographical conditions are suitable, potassium chloride or potassium sulfate can be produced by solar evaporation. Typical analyses of some of the more important sources are listed in Table 10.

Table 10. Composition of some natural brines compared with seawater (in wt %)

	Dead Sea	Wendover brine	Great Salt Lake	Seawater
K^+	0.6	0.6	0.7	0.04
Na^+	2.9	9.4	7.6	1.08
Mg^{2+}	3.4	0.4	1.1	0.13
Ca^{2+}	1.3		0.016	0.04
Cl^-	17.0	16.0	14.1	1.94
SO_4^{2-}	0.04	0.2	2.0	0.27
Br^-	0.5		0.01	0.006
H_2O	74.3	73.3	74.5	96.5

8.1. The Dead Sea

Potash production by solar evaporation began at the northern end of the Dead Sea in 1931. Later, production switched to the southern end but was interrupted by the war of 1947 – 1948. In 1952, potash production was resumed in Sodom by the Israeli State *Dead Sea Works*. The capacity was built up in several stages and now amounts to $> 2 \times 10^6$ t of potassium chloride in all the usual commercial grades [182, 183].

Brine from the lake is concentrated in evaporation ponds with a total area of ca. 90 km^2, from which the crystallized salts are recovered. Most of the dissolved sodium chloride separates out

first in the primary evaporation ponds. A mixture of carnallite and sodium chloride then crystallizes in the main production ponds. This is removed as a suspension by suction dredgers and pumped to the works where the crystals are filtered off and treated by the carnallite cold decomposition process (see Section 5.2.3). Most of the resulting NaCl – KCl mixture is then treated in a hot leaching plant (see Section 5.2.2), where potassium chloride with $> 60\,\%$ K_2O is produced in crystallizers. Part of the crop of crystals from the main production ponds is treated by a cold crystallization process developed by the Dead Sea Works. This decomposition process directly yields a product containing $> 60\,\%$ K_2O.

A potash works was started by the *Arab Potash Co.* in 1982 on the southeast bank of the Dead Sea near Safi, Jordan. Evaporation and carnallite production are carried out in a pond system with a total area of $100\,km^2$. The process resembles that of the Dead Sea Works. Magnesium chloride is removed from carnallite in a cold decomposition process, and the salt mixture formed is then treated in a hot leaching plant to give potassium chloride [182, 184].

8.2. The Great Salt Lake [185]

The Great Salt Lake is the result of the shrinkage by evaporation of the former Lake Bonneville and lies in the eastern part of the basin. It has a high salt content and is the reason for the existence of several plants that produce sodium chloride and, since 1968, potassium salts.

At the western end of the Great Salt Lake, in the Great Salt Lake Desert near Wendover, are the Bonneville Salt Flats. Here, under a salt crust, are porous sediments containing brines, which are regenerated by water from atmospheric precipitation. Potassium chloride has been produced from these brines since 1937. They are collected by a system of ditches and evaporated in ponds. A mixture of potassium and sodium chloride crystallizes, from which potassium chloride is obtained by flotation [186].

Unlike the Wendover brines, the Great Salt Lake brines contain considerable amounts of sulfate (see Table 10). The process used in Wendover cannot therefore be used here. The opportunity exists of obtaining substantial quantities of valuable potassium sulfate rather than potassium chloride, which has been carried out since 1970 in the Great Salt Lake Minerals & Chemicals Corporation (GSLM & CC) plant at Ogden on the east bank. Sodium chloride is first crystallized in the 56-km^2 pond system until the solution is saturated in potassium salts. Further solar evaporation then takes place in the main production ponds, producing a mixture containing varying proportions of kainite, carnallite, and schoenite, with small amounts of sodium chloride [187]. This mixture is converted into schoenite in the plant by treatment with recycled process brine. The sodium chloride that is not dissolved by this reaction must be removed before further treatment. This is carried out by flotation of a side stream [102]. Schoenite is then decomposed by water, which produces very pure potassium sulfate. The brine from this decomposition stage has a high potassium content and is recycled to the first stage of the process. The brine produced by the reaction at this stage is recycled to the evaporation pond. The sulfate content of the main crop of crystals is higher than the potassium content, so that further potassium sulfate can be produced by addition of potassium chloride from an external source [188].

The level of the Great Salt Lake increased so much during the 1970s and 1980s that the pond system of the Great Salt Lake Minerals & Chemicals Corporation (GSLM & CC) overflowed during 1984, and production had to stop [189]. The lake level then fell, the pond system was reinstated, and production started again in 1989.

8.3. Searles Lake [190]

In Trona, on the northwest bank of the almost dry Searles Lake, brines are obtained that contain not only sodium and potassium chlo-rides, but also considerable quantities of sulfate, carbonate, and borate ions. Recycled process brines are first added, and evaporation produces sodium chloride and the double salt burkeite [*12179-88-3*], $Na_2CO_3 \cdot 3\,Na_2SO_4$. Potassium chloride is obtained by vacuum cooling of the potassium- and borate-containing mother liquor. Part of the chloride is reacted with part of the burkeite to form glaserite, $Na_2SO_4 \cdot 3\,K_2SO_4$, an intermediate stage in potassium sulfate production. An-

other reaction used for potassium sulfate production is that of potassium borate in the end brines with sulfuric acid, to form potassium sulfate and boric acid:

$$K_2B_{10}O_{16} \cdot 8\,H_2O + 6\,H_2O + H_2SO_4 \longrightarrow K_2SO_4 + 10\,H_3BO_3$$

8.4. Other Sources

In addition to the sources mentioned under potassium sulfate, other salt lakes exist whose potassium content would appear to offer the possibility of extracting potassium salts. In 1969 at Lake McLeod in Western Australia, a works produced langbeinite, $K_2SO_4 \cdot 2\,MgSO_4$, for a short period of time but ceased operations for unknown reasons. In China, in the Qinghai Province, potassium chloride production has been carried out for several years at Tsarhan Lake by using solar evaporation. Large increases in production are planned [191].

Seawater has a low potassium content (Table 10) so that economical extraction of potassium salts is not possible. The production of sea salt by solar evaporation in salt gardens yields residual brines with increased potassium content. In some places (e.g., India), small quantities of low-percentage potassium salts are produced from these bitterns. However, economical production of potash fertilizers of marketable quality is not possible from the amounts of mother liquor available from even the largest sea salt producers.

9. Storage and Transportation

(→ Fertilizers, Chap. 8.1.)

The demand for potash fertilizers fluctuates greatly throughout the year, but because potash plants need to produce at as steady a rate as possible, large storage capacities are needed to accommodate periods of low demand. Therefore, potash plants usually have high-capacity product storage facilities. Also, in seaports, where fertilizers are loaded onto ships, the largest potash companies or their subsidiaries have large storage capacities. In both cases, long storage sheds are used, usually with walls sloping to match the angle of repose of the potash salt. The sheds are usually filled by means of conveyor belts located under the shed roof. They are emptied either by bucket loaders or scrapers that move the salt into a channel under the floor of the silo or onto a conveyor belt at the side, which carries it via sloping bands or elevators to the loading plant. More recently, especially where there is a shortage of land, round silos have been used, often arranged in rows. These too are filled from above by conveyor belts and are emptied through openings at ground level. The majority of potash fertilizer is transported in bulk in self-discharging wagons with a capacity up to 100 t, by rail, truck, or inland waterway. Transport from potash plants remote from a seaport or the main consuming area is usually by special trains that run on a fixed timetable between the potash plant and the seaport or intermediate storage facility. For example, the transport of potash fertilizers from Saskatchewan to a cargo-handling plant in Vancouver uses continuous-loop train tracks that enable 10 000 t to be delivered in 102 wagons with a capacity of 98 t each [192].

A small proportion of potash salts is supplied in sacks, usually containing 50 kg. The sacks are filled either by the supplier or at the loading plant at the seaport by automatic sack-filling machines. The sacks are usually paletized.

10. Analysis of Potassium Compounds

Potassium is usually determined gravimetrically. In the United States, it is precipitated as the hexachloroplatinate [193]. Precipitation as the tetraphenylborate is another widely used method, being the standard ISO method for fertilizers, and can be either a gravimetric or a volumetric procedure (ISO 5318 and 5310) [194]. Precipitation as the perchlorate or tartrate is seldom used. Flame photometry is used for both laboratory and process control analysis. X-ray fluorescence can be used for the analysis of solids or brines.

A review of methods recommended for potassium determination in fertilizers is given in → Fertilizers.

11. Potassium Hydroxide [195–198]

11.1. Properties

Pure, solid potassium hydroxide [1310-58-3], KOH, caustic potash, M_r 56.11, ϱ 2.044 g/cm^3, mp 410 °C, bp 1327 °C, heat of fusion 7.5 kJ/mol, is a hard, white substance. It is deliquescent and absorbs water vapor and carbon dioxide from the air. Potassium hydroxide dissolves readily in alcohols and water (heat of solution 53.51 kJ/mol). The solubility of KOH (g KOH/100 g H_2O) in water is shown below:

Temperature, °C	0	10	20	30	50	100
Solubility	97	103	112	126	140	178

The mono-, di-, and tetrahydrates are formed with water. Aqueous potassium hydroxide is a colorless, strongly basic, soapy, caustic liquid, whose density depends on the concentration:

Concentration, wt %	10	20	30	40	50
Density, g/cm^3	1.092	1.188	1.291	1.395	1.514

Technical caustic potash (90 – 92 % KOH) melts at ca. 250 °C; the heat of fusion is ca. 6.7 kJ/mol.

11.2. Production

Today, potassium hydroxide is manufactured almost exclusively by potassium chloride electrolysis. The diaphragm, mercury, and membrane processes (→ Chlorine) are all suitable for the production of potassium hydroxide, but the mercury process is preferred because it yields a chemically pure 50 % potassium hydroxide solution.

In the *diaphragm process*, a KCl-containing, 8 – 10 % potassium hydroxide solution is initially formed, whose salt content can be reduced to ca. 1.0 – 1.5 % KCl by evaporation to a 50 % liquor. Further purification is complicated, and the quality of liquor from mercury cells cannot be achieved.

In the *mercury process* a very pure KCl brine must be utilized, because even traces (ppb range) of heavy metals such as chromium, tungsten, molybdenum, and vanadium, as well as small amounts (ppm range) of calcium or magnesium, lead to strong evolution of hydrogen at the amalgam cathode. The very pure potassium hydroxide solution running off the decomposers is cooled, freed from small amounts of mercury in precoated filters, and in some cases sent immediately to the consumer as a 45 – 50 % liquor in drums, tank cars, or barges.

Since about 1985, new cell rooms for the manufacture of potassium hydroxide solution have used the *membrane process*. At present, the cell liquor has a low chloride content (10 – 50 ppm); the KOH concentration is 32 %. Before dispatch, it is concentrated to 45 – 50 % by evaporation.

Nonelectrochemical processes have been proposed for the manufacture of chlorine and potassium hydroxide from KCl by thermal decomposition of potassium nitrite in the presence of Fe_2O_3 [199].

This method involves reacting KCl with NO_2 to obtain Cl_2 and potassium nitrite, reacting the KNO_2 with iron(III) oxide and oxygen to give potassium ferrate ($K_2Fe_2O_4$), and reacting the ferrate with water to produce KOH. Another method consists of reacting an aqueous solution of KCl with NO_2 and O_2 to give Cl_2 and KNO_3, which is reacted with water in the presence of Fe_2O_3 to produce KOH.

Largely water-free, ca. 90 – 95 % potassium hydroxide (caustic potash) is obtained by evaporating potassium hydroxide solution. The residual content of 5 – 10 % H_2O is bound as a monohydrate.

Suitable evaporation processes are single- or multistage falling-film evaporators [200], Badger single-tube evaporators, or boilers connected in cascade. Heating is carried out with steam or by means of heat-transfer agents (salt melts, Dow-therm). Flash evaporators are used as the final stage in large-capacity plants [201].

To counter the strong corrosiveness of the potassium hydroxide solution and retain the purity of the caustic potash, the equipment is made largely from high-purity nickel (LC 99.2) or is silverplated. The equipment is often protected by polarization.

For dispatch, caustic potash comes on the market poured directly into drums or packed in polyethylene bags after cooling; in blocks, molded pieces, flakes, prills, and as a powder. Potassium hydroxide is classified as a corrosive material:

UN no.	1814	(for aqueous solution)
UN no.	1813	(for dry material)
GGVS/GGVE	Class 8	
RID/ADR	Class 8	

Handling is described in [202].

11.3. Quality Specifications

Potassium hydroxide solution is supplied in pure quality [total alkalinity 49.7 – 50.3 %, KOH 48.8 % (min.), NaOH 0.5 % (max.), CO_3^{2-} 0.1 % (max.)] or in technical quality [total alkalinity 49.7 – 50.3 %, NaOH 1.0 % (max.), CO_3^{2-} 0.3 % (max.)]. The contents of Cl^-, SO_4^{2-}, Fe^{2+}, and Ca^{2+} are < 30 ppm. Solid caustic potash produced from amalgam liquor has a total alkalinity (calculated as KOH) of 89 – 92 %, NaOH 1.5 % (max.), CO_3^{2-} 0.5 % (max.), Cl^- 0.01 % (max.). The values for SO_4^{2-}, Fe^{2+}, and Ni^{2+} are < 50 ppm. Caustic potash from diaphragm electrolysis has a Cl^- content of 2.5 – 3.0 % and higher content of heavy metals.

For analysis, see 12.3.

11.4. Economic Aspects and Uses

Pure-quality potassium hydroxide is used as a raw material for the chemical and pharmaceutical industry, in dye synthesis, for photography as a developer alkali, and as an electrolyte in batteries and in the electrolysis of water. Technical-quality KOH is used as a raw material in the detergent and soap industry; as a starting material for inorganic and organic potassium compounds and salts (e.g., potassium carbonate, phosphates, silicate, permanganate, cyanide); for the manufacture of cosmetics, glass, and textiles; for desulfurizing crude oil; as a drying agent; and as an absorbent for carbon dioxide and nitrogen oxides from gases.

World production is estimated at ca. 700 – 800 $\times 10^3$ t/a. Main producers are the United States [203], Germany, Japan, and France. Other important producer countries are Belgium, the United Kingdom, Italy, Spain, South Korea, India, Israel, former Yugoslavia, former Czechoslovakia, Sweden, and Romania.

12. Potassium Carbonate [195–198]

Potassium carbonate was produced in antiquity and used for many purposes. In the Old Testament, potash is mentioned in Jeremiah (written in the 7th century B.C.). ARISTOTLE describes the extraction of wood ash with water; the Romans manufactured soap from fat and potash. LAVOISIER identified potash as potassium carbonate.

The production of potash from wood ash for the manufacture of glass and soap was a flourishing industry in the Middle Ages in areas having a plentiful supply of wood such as Russia, and also in Scotland. Since 1860, potash salts have replaced wood as a raw material for the manufacture of potassium carbonate.

In Anglo-American usage, the term potash today includes potassium carbonate as well as all potassium salts, such as KCl, K_2SO_4, and $K_2SO_4 \cdot MgSO_4 \cdot x\,H_2O$, that are used as fertilizers; the potassium content is given as K_2O.

Potassium carbonate occurs in small amounts in a few African lakes (e.g., Lake Chad and in the vicinity of Lake Victoria), as well as in the Dead Sea.

12.1. Properties

Anhydrous potassium carbonate [*584-08-7*], K_2CO_3, M_r 138.21, ϱ 2.428 g/cm^3, *mp* 891 °C, is a white, hygroscopic, powdery material that deliquesces in moist air. It is readily soluble in water with the formation of an alkaline solution. The solubility of K_2CO_3 (g K_2CO_3/100 g H_2O) in water is given below:

Temperature, °C	0	10	20	30	40	50
Solubility	105.5	108.0	110.5	113.7	116.9	121.2
Temperature, °C	60	70	80	90	100	
Solubility	126.8	133.1	139.8	147.5	155.7	

On addition of acid, potassium carbonate reacts with the evolution of carbon dioxide:

$$K_2CO_3 + H_2SO_4 \longrightarrow K_2SO_4 + CO_2 + H_2O$$

K_2CO_3 forms several hydrates, of which $K_2CO_3 \cdot 1.5\,H_2O$ is the stable phase in contact with the saturated solution from 0 °C to ca. 110 °C. This hydrate (M_r 165.24, ϱ 2.155 g/cm^3) crystallizes in glassy, virtually

dust-free crystals. It is also hygroscopic and deliquesces in moist air. It is completely dehydrated at 130 – 160 °C.

12.2. Production

From Caustic Potash and Carbon Dioxide. The most important process for the manufacture of potassium carbonate begins with electrolytically produced potassium hydroxide solution. The almost chemically pure solution obtained by the mercury process (see 11.2) is reacted with carbon dioxide or CO_2-containing off-gases (flue gas, lime kiln gas).

$$2\,KOH + CO_2 \longrightarrow K_2CO_3 + H_2O$$

Solid potassium carbonate is then obtained by crystallization (under vacuum and with cooling) from liquors or in the fluidized-bed process.

In the continuous crystallization process (Fig. 50), the filtered, fresh carbonate solution is mixed with mother liquor and concentrated in several preliminary evaporators connected in series until the hydrate $K_2CO_3 \cdot 1.5\,H_2O$ finally precipitates in the crystallizer after cooling under vacuum [204]. The mother liquor is separated from the crystal suspension in hydrocyclones and centrifuges, filtered, and fed back to the process. The crystals are dried at ca. 110 – 120 °C in rotary kilns or fluidized-bed dryers and packed for sale as potash hydrate, or they are calcined at 200 – 350 °C to give 98 – 100 % K_2CO_3. Impurities such as soda, sulfate, silicic acid, and iron that concentrate in the mother liquors can be partially removed [205] by removing a partial stream of the mother liquor, which is either used for brine purification in the electrolysis process or sold as a low-grade potassium carbonate solution, or by crystallizing the double-salt $NaKCO_3$ at elevated temperature in a separate crystallization and drying process.

The resulting potassium carbonate is very pure and meets the requirements of USP, BP, DAB, and JP if the process is operated in appropriate manner.

Starting from potassium carbonate solution, prills can be produced in a combined reactor, in which spray drying and fluidized-bed granulation take place simultaneously [206].

In the fluidized-bed process, aqueous potassium hydroxide solution is sprayed into a fluidized-bed reactor from above and exposed to a countercurrent of CO_2-containing hot gas (Fig. 51) [207, 208]. Carbonization and calcination take place in the same reactor. Hard, spherical potassium carbonate prills are formed having a high packing density. The prills are discharged and sieved. The coarse grains are ground and returned to the reactor together with the very fine grains, where they act as crystallization seeds. The salable, dust-free, medium grains are cooled and packed. Because no mother liquor is formed, the quality of the potassium carbonate depends on that of the raw materials. Compared to the crystallization process the chlo-ride, soda, and sulfate contents are usually higher, but the investment and production costs are lower.

Amine Process. In the Mines de Potasse d'Alsace process, potassium chloride is reacted under pressure in autoclaves with carbon dioxide in precarbonated isopropylamine solution. Potassium hydrogencarbonate precipitates and is filtered off, carefully purified of amine by intensive washing, and dried. It can be converted to potassium carbonate by calcination. Free amine, containing carbon dioxide, is recovered from the mother liquor by distillation and recycled. The chloride, predominantly present in the mother liquor as amine chlorohydrate, is reacted with hydrated lime to give free amine and an aqueous solution of calcium chloride [209].

The use of triethylamine [210], hexamethylenimine [211], or piperidine [212] is also patented. All the processes have the disadvantage that calcium chloride liquor is obtained, which can be utilized today only to a small extent and therefore represents an environmental pollutant.

Nepheline Decomposition Process [213]. In the CIS, considerable amounts of potassium carbonate are formed as a byproduct in the nepheline decomposition process for aluminum hydroxide production. The mineral nepheline is decomposed with limestone by sintering at 1300 °C:

$$(Na,K)_2 \cdot Al_2O_3 \cdot 2\,SiO_2 + 4\,CaCO_3 \xrightarrow{1300\,^\circ C} (Na,K)_2O \cdot Al_2O_3 + 2(2\,CaO \cdot SiO_2) + 4\,CO_2$$

Alumina, portland cement, soda, and potash are obtained from the product in a complex process. The sinter product is leached with an Na_2CO_3 – NaOH solution. After filtration, a filter cake is obtained that is processed to give portland cement and an aluminate solution containing silicic acid. After precipitation of the silicic acid as alkaline aluminum silicate the purified aluminate solution is reacted with carbon dioxide:

$$2\,(Na,K)AlO_2 + CO_2 + 3\,H_2O \longrightarrow 2\,Al(OH)_3 + (Na,K)_2CO_3$$

The aluminum oxide hydrate is filtered off, and the carbonate solution is concentrated by fractional crystallization in a three-stage process and separated into sodium carbonate and $K_2CO_3 \cdot 1.5\,H_2O$.

Feldspar ($KAlSi_3O_8$) and leucite ($KAlSi_2O_6$) can also be decomposed analogously and used for alumina, cement, and potassium carbonate manufacture [214].

The magnesia process (Engel – Precht process) is of limited interest:

$$3\,(MgCO_3 \cdot 3\,H_2O) + 2\,KCl + CO_2 \longrightarrow$$
$$2\,(MgCO_3 \cdot KHCO_3 \cdot 4\,H_2O) + MgCl_2$$

In hot water the double salt ($MgCO_3 \cdot KHCO_3 \cdot 4\,H_2O$) decomposes under pressure into magnesium carbonate and dissolved potassium carbonate.

Other processes. Le Blanc process:

$$K_2SO_4 + CaCO_3 + 2\,C \longrightarrow CaS + K_2CO_3 + 2\,CO_2$$

Formate process :

$$K_2SO_4 + Ca(OH)_2 + 2\,CO \longrightarrow 2\,HCOOK + CaSO_4$$
$$K_2SO_4 + Ca(OH)_2 + 2\,CO \longrightarrow 2\,HCOOK + CaSO_4$$
$$HCOOK + KOH + 1/2\,O_2 \longrightarrow K_2CO_3 + H_2O$$

"Piesteritz" process :

$$K_2SO_4 + 2\,CaCN_2 + 2\,H_2O \longrightarrow$$
$$2\,KHCN_2 + CaSO_4 + Ca(OH)_2$$
$$2\,KHCN_2 + 5\,H_2O \longrightarrow K_2CO_3 + 4\,NH_3 + CO_2$$

These processes are uneconomical today because of high energy consumption and poor product quality, and are no longer used.

In the decomposition of chromium ores with potassium hydroxide solution, a chromate-containing potassium carbonate is obtained as byproduct. The production of potassium permanganate yields considerable amounts of potassium carbonate solution [215].

Organic raw materials, such as sunflower stalks, molasses, and suint, are used to a small extent for potash manufacture. They are ashed, leached with water, and processed to potash by fractional crystallization and calcination [216].

Ion-Exchange Process [217, 218]. An acidic ion exchanger loaded with ammonium ions is charged with KCl solution, K^+ being absorbed and an ammonium chloride solution running off. The ion exchanger is then eluted with an excess of ammonium carbonate solution (regeneration of the exchanger). The eluate, a K_2CO_3 – $(NH_4)_2CO_3$ solution, is separated by thermal cleavage to give ammonia and carbon dioxide. The ammonium chloride is reacted with magnesium hydroxide to give magnesium chloride and ammonia, which is recycled.

12.3. Quality Specifications and Analysis

Depending on the intended use, potassium carbonate is offered in varying commercial forms and degrees of purity: as granules, as powder, and as potassium carbonate hydrate ($K_2CO_3 \cdot 1.5\,H_2O$). The material manufactured from mercury-process potassium hydroxide solution is of high purity, particularly with respect to chloride content. In the amine process, the chloride content is higher and the sodium carbonate content lower, while nepheline decomposition gives high sodium carbonate contents and relatively high sulfate contents (Table 11).

Analysis. The *total alkalinity* includes $K_2CO_3 + KOH + Na_2CO_3$; it is determined with $0.5\,N\,H_2SO_4$ by potentiometric titration or with a methyl orange indicator (change to brown-red). Sodium is determined by flame photometry. The *chloride content* is determined by turbidity measurement after addition of $AgNO_3$. The *sulfate content* is determined by ion chromatography or gravimetrically after precipitation as barium sulfate. The *metal content* is determined by atomic absorption spectroscopy or photometrically by complex formation (Fe^{2+} as sulfosalicylate, Si^{4+} as the molybdato complex, Cu^{2+} as pyrrolidinodithiocarbamate, and Ni^{2+} as the diacetylglyoxime complex). Test methods for *photographic-grade* potassium carbonate, anhydrous are described in ISO 3623-1976 (E).

12.4. Storage and Transportation

Potassium carbonate is stored in bunkers; the ventilation air must be dry because of the hygroscopicity of the product.

Table 11. Analyses of calcined potassium carbonate of varying origin (data in %, remainder H_2O)

	From potassium hydroxide solution				
	Mercury process		Diaphragm	Amine	Nepheline
	Crystallization	Fluidized bed	process	process	decomposition
K_2CO_3	98.0 – 99.8	98.5 – 99.5	97 – 99	99	97.5 – 98.5
Na_2CO_3	0.1 – 0.5	0.1 – 0.5	0.5 – 1.0	0.01	0.1 – 1.0
Cl	0.001 – 0.002	0.004 – 0.013	0.2 – 1.0	0.19	0.01 – 0.03
SO_4	0.003 – 0.005	0.005 – 0.013	0.005 – 0.010		0.25 – 0.60
Si + Ca	0.005	0.006	0.010	0.009	
Fe	0.0003 – 0.0005	0.0002 – 0.0006	< 0.0005	< 0.0024	0.0007 – 0.0021

Silo vehicles and bulk containers are used for dispatch to bulk customers. Smaller amounts are packed in polyethylene valve sacks of 25 – 50 kg. The material is not hazardous; for pharmaceutical use it is classified as GRAS (generally recognized as safe) by FDA [219].

12.5. Economic Aspects and Uses

The glass industry is the most important consumer of K_2CO_3. Large amounts are also required for potassium silicate manufacture.

Potassium carbonate is used for many organic syntheses. Numerous inorganic and organic potassium salts are manufactured from potassium carbonate (potassium phosphate, bromide, iodide, dichromate, cyanide, and ferrocyanide); in addition it is a starting material for drying, neutralization, and condensation agents. As a regenerable absorbent for carbon dioxide, hydrogen sulfide, and sulfur oxides, it is attaining importance in environmental protection. Potassium carbonate is used as a fertilizer for acidic soil.

Other users are the electrical industry, the dye industry, the printing trade, the textile industry, the leather goods industry, and the ceramic industry. Soft soap manufacture has lost its earlier importance as a customer. Potash solutions are used as fire retardants and as cooling brines (freezing point − 36 °C at 576 g/L=40.5 wt % K_2CO_3).

The food industry uses potassium carbonate as a leavening agent in baked goods, as a debitterizing agent for cocoa beans, and as an additive for drying raisins. Potash in DAB quality is frequently used in the pharmaceutical industry as a raw material and auxiliary.

The most important producer countries for potassium carbonate are the CIS, France, Germany, the United States, and Japan. Other producers are Israel, Spain, India, South Korea, Belgium, Italy, former Yugoslavia, and China.

13. Potassium Hydrogencarbonate

[195–197]

13.1. Properties and Production

Potassium hydrogencarbonate [*298-14-6*], $KHCO_3$, M_r 100.12, ϱ 2.17 g/cm^3, is a white, crystalline powder that is sparingly soluble in water and insoluble in alcohol. When heated above 120 °C, it decomposes into potassium carbonate, water, and carbon dioxide.

It is manufactured industrially by passing carbon dioxide into concentrated potassium carbonate solutions or exposing these to a countercurrent of purified, cold flue gas in trickle towers (overcarbonization). Because of its low water solubility (22.4 g of $KHCO_3$ in 100 mL of H_2O at 20 °C) it precipitates in crystalline form, is separated by centrifugation, and dried at ca. 110 °C. In some potassium carbonate production processes, potassium hydrogencarbonate is obtained as a precursor (see 12.2).

The total alkalinity of the industrial material, calculated as $KHCO_3$, is at least 98 – 100 % [$KHCO_3$ 98 % (min.), Na^+ 0.1 % (max.), Cl^- 0.01 % (max.), SO_4^{2-} 0.02 % (max.); for analysis see potassium carbonate, p. 98].

13.2. Uses

Potassium hydrogencarbonate is used in the manufacture of fire extinguisher powders, in the

food industry as a leavening agent, and in the chemical and pharmaceutical industry for the manufacture of high-purity potassium carbonate and other pure potassium salts. Producing countries are the United States, Germany, and France.

1. Introduction

1.1. Production Routes

Powder metallurgy (PM) is a technique used to transform metal powders into consolidated material. Production methods include the pro-cessing steps [1–5]: powder preparation (Chap. 2), powder conditioning (Chap. 4), shaping, consolidation (Chaps. 567), and secondary operations (Fig. 1). The final products may or may not contain pores.

Powder production methods include chemical reactions from precursors or disintegration of bulk solids or liquids. The main *powder conditioning steps* are sieving, blending, and the addition of binders or pressing aids.

Shaping and hot consolidation can be realized in two consecutive steps or in a single shaping – hot consolidation step. In *two-step shaping – consolidation* the powders are shaped at ambient temperature by (almost) pressureless methods into preforms or by compacting in dies under an uniaxial load or in thin-walled capsules

Figure 1. Basic steps of PM production

under isostatic pressure. These shaping methods are supplemented by indirect shaping methods (e.g., machining of loosely-packed and slightly sintered bulks).

Parts shaped at room temperature contain pores between the individual particles (usually porosity 10 – 60 vol %). The purpose of subsequent sintering (heat treatment below the melting temperature of the major constituents of the parts) is to initiate and enlarge the solid contacts between the particles. The driving force for contact growth is the reduction of the sum of the surface and interfacial energies. Depending on the geometric arrangement of the particles and the active transport mechanism, the same driving forces may lead to shrinkage or elimination of the pores. Low- or zero-porosity parts are also obtained by double sintering in which two pressing and sintering cycles are used.

Single-step shaping – hot consolidation methods simultaneously apply elevated temperature, external compacting, and/or forming pressures to obtain high or full density. Typical direct consolidation methods are hot pressing, hot isostatic pressing, extrusion, and rolling. Products of the two-step consolidation route (sintered parts) are sometimes used as preforms for direct consolidation methods such as hot isostatic pressing and in particular sinter forging.

Some of the *secondary operations* are common to non-PM parts (e.g., hardening by heat treatment, joining, and surface modification).

Figure 2. Initial powder size and dimensional change during sintering for different types of products
V/V_{TD} = relative volume; V_{TD} = theoretical volume

Coining operations and pore filling by steam reaction treatments or by infiltration with metals or polymers are unique to sintered porous parts.

1.2. Product Groups

PM products are classified as follows:

1) Structural parts (Chap. 8)
2) High-performance materials (Chap. 9)
3) Parts with inherent functional porosity (Chap. 10)

These products require different initial powders and different dimensional changes during consolidation (Fig. 2).

Structural Parts. Competitive structural PM parts with an accurate shape and size are cheaper than equivalent parts produced by machining cast and wrought bulks (Fig. 3) [6], [7].

Major arguments for the production of structural parts by PM are exact size and shape, exact weight, negligible machining, high material efficiency, and low energy consumption.

Figure 3. Structural PM parts for the automotive industry

The main emphasis is put on the control of dimensional changes occurring during sintering to avoid subsequent extensive machining of the sintered parts. The dimensions are well controlled if shrinkage or swelling during pressureless sintering are kept small; as a result the porosities after cold compaction and sintering should be approximately equal. The simultaneous requirements for minimal dimensional changes and a high final density (required for good mechanical properties) at low powder prices are satisfied by the use of coarse, unalloyed powders ($> 100\,\mu m$) which are cold compacted into compacts with density and shape similar to those of the final parts. Mixtures of powders are usually used to obtain alloys.

Formation of chemical bonds between the particles and homogenization of the alloying components during sintering yields reasonable mechanical properties as a result of solid-solution hardening, precipitation hardening, or the formation of martensite. In most cases the final material properties of PM parts are slightly inferior to the properties of parts machined from cast and wrought bulks due to a residual porosity of 5 – 15 %.

Metal-injection molding (MIM) is used for production of small structural PM parts with complex shapes. A blend of binder (e.g., waxes) and fine powder is injection molded into dies. After ejection and binder removal the porosity of the parts has to be reduced to a few percent by sintering. Extensive shrinkage occurs, requiring fine powders and limiting the dimensional accuracy of the final parts [8], [9]. The argument for the use of MIM is the lower price compared to machining or precision casting.

Figure 4. Hot isostatically-pressed stainless steel valve component for off-shore oil exploitation

High-Performance Materials. PM can be used to produce parts or semifinished parts made of high-performance materials. Major technical arguments for using PM instead of other methods are based on material properties such as high melting point, insufficient machinability, and microstructures that cannot be obtained via the casting route (phase combination and distribution).

Fine-grained, segregation-free material is obtained as well as materials and phase combinations that cannot be prepared by foundry procedures. Examples are refractory metals (W, Mo) [10], hard metals (WC – Co) [11], heavy-metal alloys (W – Ni – X) [12], hard magnets (Co – Sm, Fe – Nd – B), and many "high-tech" ceramics [13]. In the two-step shaping – consolidation route, these high-performance materials are sintered to complete density, usually at a small grain size. This production route generally requires fine starting powders and powder mixtures that accelerate

shrinkage (e.g., by forming a limited amount of liquid phase [5]).

High-performance materials are processed by the single-step shaping – hot consolidation method if they are produced from powders or powder mixtures that have an unsufficient sinterability (e.g., metal – matrix composites) or require low processing temperatures (e.g., rapidly solidified atomized powders) if the metastable microstructural features are to be maintained [14].

Very large parts with microstructures of an extremely long-range homogeneity (Fig. 4) can be obtained by hot isostatic pressing of coarse powders to near net shapes; material waste due to machining is minimized [15]. The argument that PM single-step shaping – consolidation is used to obtain superior high-performance material properties can be replaced by an economic argument which justifies the use of single-step shaping PM when material costs and the ratios of starting to final weight of the parts increase.

Parts with Inherent, Functional Porosity. Particles with shapes ranging from spherical powders to elongated fiber chunks or combinations with metal fiber fleeces are used for parts with inherent, functional porosity [16]. Sintering is stopped when contacts between adjacent particles provide sufficient mechanical strength, but interconnected (open) porosity still exists. This means that pore channels still connect the surface to the interior of the parts. Examples are electrodes of cardiac pacemakers, noise-reducing filter elements, and self-lubricating bearings. For the majority of these parts PM is the only cost-effective production method.

1.3. History and Developments

The Iron Pillar of Delhi illustrates the early use of a PM-related technique in the 2nd century B.C. Iron-rich nuggets were separated from nonmetallic material by warm forging and then sinter-forged into a pillar weighing more than 6 t. Similar techniques were used for martial weapons such as the Damascus swords. Platinum powder from platinum sponges was consolidated by PM techniques between 1800 and 1860 in Russia. Around 1900 COOLIDGE developed a production method for tungsten and molybdenum heating filaments used in incandescent lamps. In the 1920s hard PM materials (e.g., WC – Co hardmetal) were developed and pro-duced. Self-lubricating PM bearings based on bronze and brass penetrated the market in the 1930s. Sintered magnets and ceramic cutting tools followed shortly after and the technology to produce parts made of niobium, zirconium, titanium, and rhenium became available in 1940. Sintered structural parts, made mainly of ferrous materials, were developed and applied at the same time. Development of new PM materials and processing techniques was boosted after the World War II. Heating elements from $MoSi_2$ oxide-dispersion-strengthened alloys (ODS) on the basis of aluminum, nickel, and titanium alloys from rapidly quenched powders or aluminum composites are examples of a broad variety of materials developed for applications in the nuclear, electronics, aircraft and space industries. Continuous progress in press technology and starting powder quality has led to structural parts of high precision and complex shapes.

Developments in sensor and control techniques of presses and sintering furnace atmospheres [17], [18] will expand the production of hardenable, structural, ferrous parts for high-strength applications. The cheaper PM production route is increasingly being applied for production of multifunctional parts and parts with complex shapes not particularly suitable for the PM method by using secondary operations, especially machining and joining.

PM-generated materials are expected to play a key role worldwide as high-performance materials for critical applications in technologically advanced products such as high-speed trains or space planes. Major progress is also expected from hybrid technologies, where advanced PM processing is combined with other techniques such as chemical vapor deposition (CVD) . An example is the development of ultrafine-grained, hard-metal parts which have superior properties compared to standard qualities. New ultrafine powders are processed to cutting chips by hot isostatic pressing and subsequently CVD-coated with TiN-based surface layers [19].

1.4. Economic Aspects

Metal powder shipments in 1987 (without former Eastern Bloc) follow [20]:

Iron and steel	470 000 t
Copper and copper alloys	45 000 t
Aluminum	50 000 t
Stainless steel	15 000 t
Nickel	40 000 t
High-speed steels	10 000 t
Tungsten and tungsten carbide	25 000 t
Total shipment	655 000 t

By far the largest quantity consists of ferrous powders with copper and nickel as the main alloying powder additives for PM steel production. The major portion (ca. 65 %) of the ferrous parts is supplied to the automotive industry. The state of the ferrous PM industry is therefore intimately coupled with the economic situation of the automotive industry [21].

The second most important PM branch comprises hardmetals. Their annual gross product is approximately equal to that of the ferrous parts PM industry.

2. Powder Production

Powders for PM production are produced by mechanical, chemical, and physicochemical methods. The raw materials and the production method determine the size, size distribution, shape, extent of impurities, and the price of the powder [1], [22].

2.1. Mechanical Methods

Mechanical disintegration may be applied to metallic solids or melts.

2.1.1. Mechanical Disintegration of Melts

Atomization. During atomization, free-falling or confined liquid metal streams are disintegrated by high-pressure gas jets or liquid jets (predominantly water) into small melt ligaments and fine droplets (Fig. 5). The usual gas or liquid jet pressures (gas atomization < 3 MPa, water atomization < 15 MPa) result in average powder sizes of 30 – 100 µm. High-pressure atomization (8 – 60 MPa) and special methods (e.g., ultrasonic gas atomization) yield average particle sizes between 3 and 30 µm [22–26].

Figure 5. Principal arrangement of an atomizer
a) Melt crucible; b) Induction coils; c) Melt stream; d) Gas or water

Hydrodynamic vertical interaction between the gas jets and the metal stream is based on Taylor instabilities, parallel interaction results from shearing of the melt crests. Similar disintegration principles hold for the water – melt interaction. Water jets may also disintegrate prior to interaction and splash on the melt stream surface as individual water droplets [26], [27]. After penetrating the melt these droplets form collapsing vapor bubbles which disintegrate the melt stream by thermal breakup.

One of the most popular empirical formulas used to estimate the influence of processing parameters on the average particle size d_m is given for gas atomization by LUBANSKA [28]

$$d_m = K \frac{\eta_m}{\eta_g} \left(1 + \frac{V_m}{V_g}\right)^{1/2} \quad (1)$$

where η_m and η_g are the dynamic viscosities of the melt and the gas stream, respectively, and

V_m/V_g represents the mass flow ratio of the melt stream and the gas jet. Fine powders require the transmission of a high momentum from the gas jet to the melt stream and a high ratio of the momentum to the melt mass. An increased impulse is obtained by increasing the gas jet pressure and/or by using confined nozzle systems where the gas jets and the melt stream are guided closely together before interaction starts. The powder size distribution of atomized powder can usually be described by a logarithmic normal distribution [29].

The atomization conditions also determine the shape (morphology) and the internal microstructure of the powders. The atomizing media may form reaction products (e.g., oxides or hydroxides) at the powder surface which hinder the spheroidization of the initially irregular melt ligaments. Air and water atomization are especially susceptible to the formation of reaction products and irregularly shaped powder, in contrast to protective gas atomization with helium, argon, or nitrogen.

Irregular powder is also obtained when solidification starts before spheroidization is complete. Powders that are atomized by liquids cool more rapidly and therefore often show irregular shapes. Powders that are atomized with protective gases have lower cooling rates and minor surface reaction products, they are therefore usually spherical.

The cooling rate in a droplet dT_d/dt during gas atomization is determined by the droplet size d_d, the heat-transfer coefficient h, the thermal conductivity K_m, and the heat capacity of the melt c_{pm}:

$$dT_d/dt = \frac{6h\Delta T\Omega}{c_{pm}d_d} \tag{2}$$

where ΔT is the temperature difference between the droplet and the atomization medium and Ω is the molar volume of the melt.

$$h = (2K_d/d_d) + 0.6\,(\Delta v/d_d)^{1/2} \cdot \left(K_m^2 c_{pm}\right)^{1/3} (\varrho_g/\eta_g)^{1/6} \tag{3}$$

where Δv is the velocity difference between the droplet and the atomization medium, and ϱ_g and η_g are the density and dynamic viscosity of the atomization gas, respectively [30]. The cooling rate is independent of the thermal conductivity in the interior of the droplet, i.e., the temperature gradients in the small droplets are vanishingly small. Typical cooling rates in argon-atomized copper droplets with diameters of 100 µm and 10 µm are 5×10^3 K/s and 5×10^5 K/s, respectively. During water atomization cooling rates are one to two orders of magnitude higher.

Fragmentation by Centrifugal Processes. A thin liquid film on a rotating electrode or disk is fragmented by instability caused by centrifugal forces [31]. The surface tension due to the specific surface energy and the curvature of the liquid surface are restraining forces. Higher centrifugal forces and a slower rate of melt supply lead to finer powders.

Particles produced by centrifugal processes show a narrow size distribution. Their average size is much coarser, however, than that of gas- or water-atomized powder. Centrifugal methods are often applied for high-melting alloys (W, Pt – Ir alloys) and for alloys which react in the molten state with the crucible materials (Ti alloys).

2.1.2. Mechanical Disintegration of Solids

The mechanical disintegration of solids is decreasing in importance as a primary powder production process. Nevertheless, it is still of importance as a secondary process (e.g., to obtain defined particle-size distributions for brittle powders, to destroy aggregates in ceramic and refractory metal powder, or to recycle hardmetals). Interaction between the mill and the powder involves microforging, fracture, and agglomeration. Typical mills are tumbling ball mills, vibration ball mills, attrition ball mills, hammer and rod mills, and the coldstream impact process [1]. See also → Size Reduction.

High-energy milling in tumbling ball mills or attritors is a new method. Large rotating cylindrical drums contain the powder and milling balls which fall onto the powder leading to microforging (strain hardening and rejoining) and fracture of the powder particles. The average particle size approaches a constant value which increases with the ductility of the powder and the milling temperature [32], [33].

For ductile metal powders average particle size is usually > 100 µm. Brittle ceramic or

metal powder may be $< 1\ \mu m$. Liquid milling additives, e.g., 2-propanol reduce the average particle size. Frequent fracture and rewelding of the powders refine their microstructures and allows (1) production of "alloyed" powder by milling mixtures of different elemental powders or (2) the working of dispersions of fine hard particles (e.g., ZrO_2 or Al_2O_3) into a metal matrix [34], [35].

The coldstream method is based on the collision of fine powder particles which are transported in a gas stream to a target plate. This method is used particularly for recycling hardmetal under clean conditions. The jet-mill method is based on the counterflow of two particle-loaded gas streams. Particles fracture when they collide with each other.

Mechanical disintegration increases the dislocation density in the metal powders up to $10^{15}\ m^{-2}$ and reduces their compactability. In many cases subsequent heat treatment is applied to soften the milled powders before compaction.

2.2. Physicochemical Methods

The physicochemical methods depend on the controlled variation of chemical and physical parameters, such as pressure, temperature, and electrical current to obtain powders of metal elements, alloys, or compounds. The carbonyl and electrolytical methods are most frequently applied.

Carbonyl Method. A number of metal compounds (e.g., carbonyls and chlorides) decompose under certain conditions of pressure, temperature, and time into gas and fine-grained metal powders that are often of high purity and excellent sinterability. The carbonyl method is mainly used for the production of iron and nickel powders (→ Iron Compounds, Chap. 3.5.; → Nickel, Chap. 6.3.) [36]. Scraps of metal (metal junk) are reacted with carbon monoxide at high pressure (30 MPa) and temperature (200 – 250 °C) to give metal carbonyls. After distillation the metal carbonyls are decomposed at lower pressures in the same temperature range to form mostly spheroidal powders (size 1 – 10 μm). The impurity content of silicon, phosphorus, sulfur, manganese, and copper is in the low ppm range. However, the contamination due to carbon is 0.1 wt % and that of oxygen is 0.1 wt %.

Electrolytical Methods. Electrolytical powder production from aqueous solutions is mainly used for copper, iron, nickel, and cobalt powder [37]. Metal cations are obtained from dissolving anodes or appropriate electrolytes. The powders formed at the cathode are usually of high purity but brittle and require a soft annealing to improve their compressibility.

Average particle size, size distribution, and shape are determined by the current density at the cathode, the temperature, concentration, acidity, and the vigor of stirring of the bath. Dendritic particles are usually obtained. Copper powder, for example, is obtained by dissolution of copper anodes into acidic $CuSO_4$ electrolytes and subsequent reduction of the Cu^{2+} cations at the cathode (→ Copper, Chap. 6.4.) [38]. Cobalt powder is precipitated from $CoCl_2$ (→ Cobalt and Cobalt Compounds, Chap. 5.), and nickel from aqueous $NiSO_4$ solutions (→ Nickel, Chap. 6.2.1.). The possibility of precipitating metal alloys has been documented for copper alloys but is less common [39].

Highly reactive metal powders are electrolytically precipitated from molten salts. Appropriate choice of the parameters for the electrolysis of titanium, niobium, and tantalum powders provides flaky powders which are used for the production of capacitors (Nb, Ta). Beryllium powder is obtained by electrolysis of a molten $BeCl_2$/NaCl bath at 330 – 380 °C [40].

Other Physicochemical Methods. Reduction of an aqueous solution of nickel amine sulfate with hydrogen at 1.4 MPa and 200 °C is known as the Sheritt – Gordon process [41]. To start precipitation the solution is seeded with fine nickel particles and catalytic ferrous sulfate. Variation of processing parameters allows the removal of accompanying alloying elements (e.g., copper and cobalt) by selective reduction. See also → Nickel, Chap. 6.4.

2.3. Chemical Methods

Reduction of Metal Compounds. Approximately half of the amount of ferrous powders used in the PM industry is produced by the

reduction of magnetite (Fe_3O_4) with carbon. Magnetite, coke, and lime (lime binds the sulfur impurities from the magnetite and coke) are placed into silicon carbide saggers (reaction vessels) which are conveyed through a fuel-fired tunnel kiln. The carbon monoxide produced from the coke reduces the ore to iron at ca. 1200 °C. Subsequent milling, sieving, and final annealing in hydrogen result in irregular sponge-iron powder (particle size 40 – 150 µm) [42].

Other powder production processes involving the reduction of solid compounds by gases, metals, carbon, or compounds include the reduction of WO_3 and MoO_3 with hydrogen [43]. This method is also applied to a small extent for iron, cobalt, nickel, and copper powders.

Titanium powder is obtained by the Kroll process. Titanium chloride vapor is heated above 800 °C and reacted with liquid magnesium forming magnesium chloride and titanium metal. The magnesium chloride is removed by vacuum sublimation yielding a titanium sponge which is mechanically disintegrated into powder. See also → Titanium, Titanium Alloys, and Titanium Compounds.

Carbide Powder. Tungsten carbide powder is the major raw material for cemented carbides (Section 9.4). Powder (particle size 0.5 – 5 µm) is manufactured by heating an intimate mixture of tungsten and carbon powders in graphite tube furnaces in a hydrogen atmosphere at 1400 – 2000 °C (→ Carbides, Chap. 2.1.) [44], [45]. TiC and TaC are obtained from mixtures of their oxides with soot (i.e., of TiO_2 and Ta_2O_5 with C), heated in vacuum to 2300 and 1700 °C, respectively (→ Carbides, Chap. 2.2. → Carbides, Chap. 2.3.). The reaction products are broken up in jaw crushers and milled into powder in carbide-lined ball mills.

3. Powder Properties and Characterization

The economical use of the powders often requires their characterization according to the following criteria:

1) Bulk and surface composition
2) Shape, size, and microstructure
3) Technical properties

Bulk and Surface Composition. The chemical composition of the powders is determined by usual analytical methods which, however, yield average values; the composition of individual particles may still vary widely. The large specific surface area of fine powders requires distinction between internal composition and surface contamination. Typical surface contaminants are adsorbed gases or oxide/hydroxide scales which are analyzed by Auger electron spectroscopy [46]. Testing for hydrogen loss provides a guide to the oxygen content. The amount of acid-insoluble, nonmetallic inclusions can be estimated by dissolving the metal in mineral acid.

Table 1. Measurement methods for particle size and particle-size distribution

Method	Particle size, µm
Microscopy

Low-angle scattering	< 0.05
Surface analysis	
BET method	< 1.0
Gas permeability analysis	< 40

Shape, Size, and Microstructure. *Powder morphologies* are qualitatively documented by scanning or transmission electron microscopy (for extremely fine powders). Quantitative morphology description by Fourrier analysis has not found commercial application [47].

A variety of methods are available for the determination of the average particle size and the particle size distribution (Table 1). See also → Particle Size Analysis. An important technical approach for the determination of the *average particle size* is the gas-flow technique em-

ployed in the Fisher subsieve sizer [48]. The pressure drop of gas passing through a slightly tapped powder bed depends on the specific surface area of the powder. The average particle size is calculated from the measured specific surface area. Other techniques are line broadening in X-ray diffraction measurements and the adsorption of noble gases by the BET method [49].

For many applications the *particle size distributions* are also required. The simplest method is sieving in a sieve column with a mesh that decreases from top to bottom. The method yields approximate results and is applicable only to powders $> 30\,\mu m$. Air classification methods are also used.

Sedimentation in liquids is based on the principle that particles move under constant acceleration (gravity or centrifugal) in viscous media after an initial period with a constant velocity which increases with their size. The time-dependent attenuation of white light or finely collimated X rays transmitted through settling suspensions is used to measure the particle size distribution [49], [50].

Field distortions caused by individual particles are measured by following changes in the electrical conductivity of electrolytes (electric sensing zone [51]) or by the light blockage principle (obscuration [52], [53]). The most frequently used method depends on the scattering of laser light. When coherent monochromatic laser light is scattered by small particles the angular intensity distribution of the diffraction pattern depends on the particle size. Scattering by particles with sizes between 2 and $300\,\mu m$ is analyzed by Fraunhofer diffraction. The Mie scattering theory is applied to sizes ranging from 0.3 to $2\,\mu m$. Very fine powders ($0.1-0.5\,\mu m$) are analyzed by the scattering of chromatic light perpendicular to the direction of the main beam [54].

Technological Properties. Technological properties of the powders are flow behavior, apparent density (filling behavior and tapping response), compressibility, and compactability. They are tested with methods that simulate practical conditions [55].

Flow behavior (flowability) improves with the integrity (compact shape) of the individual particles and their sphericity. The flow behavior of fine powders also depends on the surface properties and atmospheric humidity which may result in the formation of condensates in particle contact areas [55], [56]. These liquid bridges exert high capillary forces on the particles which reduce the flow capability compared to a dry, anhydrous powder. Very fine powders (e.g., ceramics, refractory metals, or carbides) usually possess a very limited flowability which can be measured in a funnel of defined geometry (Hall flowmeter) [57]. They are conditioned into flowable agglomerates (Chap. 4).

Good filling behavior and response to tapping provide high apparent or green densities (green density denotes the density after compaction). Powders with high apparent densities offer beneficial conditions for compaction into parts due to the smaller ratio of the initial to the final part size. The *apparent density* is measured as the mass of powder which fills a given container under free flow. The apparent density of a spherical powder is superior to that of an irregu-lar or dendritic powder. Large powders are superior to fine powders [58]. Broad particle-size distribution is superior to powders of uniform size [59]. Additional tapping or vibration increases the apparent density [57].

The *compressibility* is defined by the relative green density obtained by compacting a powder at a certain pressure, and is usually tested in dies which simulate the geometries of real applications. At the same pressure powders of ductile material yield higher densities than brittle powder. Impurities can reduce the compressibility dramatically (e.g., N_2 in Fe) [23]. Coarse powders ($60-150\,\mu m$) are more easily compressed than fine ($0.5-10\,\mu m$) or ultrafine ($< 0.5\,\mu m$) powders. The *compactability* of a powder is defined by the green strength, the edge strength, and the density in the neutral zone of the compacts [23].

4. Powder Conditioning

Powder conditioning of ferrous powders is frequently performed by the powder producer who delivers a ready-to-sinter powder. Some steps of powder conditioning for high-alloyed steels, hardmetals, and special low-volume production batches (e.g., hard magnets) are mostly done by the part manufacturers. Powder conditioning includes

1) Milling, annealing, and classification
2) Addition of binders and pressing aids
3) Blending
4) Agglomeration and granulation

Milling, Annealing, and Classification. Many production methods, such as the chemical reduction of Fe_3O_4 or WO_3 (Section 2.3), provide metal powder cakes which have to be disintegrated by soft milling to obtain powder suitable for PM production (Section 2.1.2).

The mechanical strain hardening of the powder during milling and uptake of humidity or oxidation during improper storage require a softening or reduction annealing at temperatures below the sintering temperature of the powder. Typical reduction temperatures for copper, nickel, and iron powder in a dry hydrogen atmosphere are 250, 650, and 700 °C, respectively [60]. The particle-size distributions of as-produced or granulated powders usually do not result in optimal flowability, filling density, and sintering be-havior. Different size classes are obtained by sieving, wet sedimentation, or air classification of the powder (Chap. 3), thus removing unfavorably small or large particles. Particle-size distributions with optimal properties are generated by mixing different powder size fractions.

Binders and Pressing Aids. Addition of binders and pressing aids reduces friction between the particles and between the powder and the pressing dies [61]. This results in higher, more homogeneous pressing densities; extended tool life; and an increased cohesiveness, i.e., reduced susceptibility to the formation of cracks or laminations during ejection from the pressing dies [62]. The pressing aids (usually zinc stearate) for ferrous structural parts are added at levels below 1 wt %. The common additive for hardmetals is paraffin which is added at levels to several weight percent [45]. These additives decompose during the sintering operation in the preheating zone of the furnace (see Fig. 13). Binders (e.g., wax) are added at levels of up to 45 vol % in metal injection molding [63], [64].

Blending. Different powders are blended by dry mixing or mixing of suspensions. Mixing quality depends on the loading, the rotational speed, and the type of the blender (usually double cones and tumblers). A statistical distribution is often not achieved if small and large, spherical and irregular, or low- and high-density powders are blended.

Demixing during further handling of ferrous powders is avoided by slight sintering of fine alloying powder particles onto the surface of the coarse iron particles (Distalloy) [65].

Agglomeration and Granulation. Micrometer-sized powders usually show inadequate flow and mixing behavior. For processing of hardmetal or ceramics, flowable powder agglomerates are produced by agglomeration, spray drying, or granulation. Bonding forces between the powder particles are provided by solid-state particle contacts, capillary forces at liquid menisci, adhesive binders, or van der Waals forces [66].

During *agglomeration* the powder particles are moved in tumbling cylinders or on inclined plates. Agglomerates form due to joining of fine particles to the surface of agglomerate nuclei. Friction among agglomerates yields spherical shapes. The cores of the agglomerates usually have a lower density than the peripheries [67].

During *spray drying* a liquid suspension (in water or organic solvents) of fine particles is atomized into fine droplets [68]. The water or solvent evaporates during free flight of the droplets which are transformed into dry agglomerates.

For *granulation* fine powder is slightly compacted into a cake-like block which is subsequently pressed through a sieve with a mesh size $>100\,\mu m$.

5. Pressing and Forming at Ambient Temperatures

Powders are consolidated to obtain parts or semifinished products with defined shape and density. Densification and forming for the two-step consolidation route (Fig. 1) aim to provide intermediate products with a density and strength that are sufficient for further handling and result in satisfactory properties after further processing. Densification and/or forming are performed at ambient temperature, most frequently by uniaxial pressing (Section 5.1). Cold isostatic pressing (Section 5.2) or injection molding (Section 5.3) is used for special

purposes. Less common are powder rolling or extrusion at ambient temperature (Section 5.2). The parts are subsequently further consolidated, most frequently by sintering, to give structural parts or semifinished products composed of high-performance materials. In some cases the preconsolidated parts are used for subsequent powder forging or hot isostatic pressing.

Shaping and consolidation are characterized by [69]

1) Initial rearrangement of particles which yields a denser packing without major particle deformation
2) Plastic deformation of particle contacts related to the approach of the particle centers, and increase both of the average contact area and the average number of contacts per particle [70]
3) A decrease in the further compressibility of the powder associated with increasing density is caused by the pressure decrease in the enlarging contacts and by deformation hardening [71]

Although, theoretical equations relating compact density and applied pressure exist [e.g., 70], empirical relations with fitting parameters are common in industrial practice. For structural parts the Konopcky relation [71]

$$P = C \ln U_0/U$$

is often used, where P is the compaction pressure, C is a constant to be determined for a given number of compactions, and U_0/U is the ratio of initial to final porosity after pressing with P. More detailed information on densification in different regions of the dies, resulting in optimized compaction parameters and die design, is given in [72–75].

5.1. Uniaxial Pressing

Powder is unidirectionally compacted in rigid dies with profiles that are perpendicular to the pressing axis and resemble the shape of the final part. The pressing tool set consists of the die, upper and lower punches, and possibly core rods (Fig. 6). The integral or split die is usually automatically filled by a powder-filled tube (Fig. 6 a) that sweeps over the die plate with the upper punch removed. Compaction is achieved by vertical movement of the upper (6 A) or the upper and lower (6 B) punches with a fixed (6 A, B, C, D) or floating (6 E, F) die arrangement. The green compact is ejected either by the lower punch moving upward (6 C, D, E) or by pulling the die downward (6 F). The ejected compact is removed either by the sweeping filling tube or by a separate fork.

During the movement of the punches, friction between the powder and the die walls leads to a decrease of the pressure transmitted into the powder. Maximal press densities are therefore measured close to the moving punches (6 C – F). Lowest densities are found in regions of minor displacements between the powder bed and the die walls, e.g., close to fixed punches in a single moving punch – fixed die arrangement (6 C) or in the central area (neutral zone) between two moving punches in a fixed (6 D) or floating (6 E, F) die [75]. The floating die is displaced by the friction forces between the moving powder bed and the die walls. Local variations in compact density often result in crack formation during ejection (elastic relaxation) and the loss of the initial compact shape as well as possible crack formation during sintering (differential sintering).

Uniaxial compaction of parts with different thicknesses in the pressing direction requires split punches to maintain a constant densification ratio, i.e., a constant ratio between the filling height and final local height of the compact. Movement of the split die is controlled by mechanical, pneumatic, or hydraulic driving systems which are precisely tuned by sensor systems [76]. Parts with severe undercuts are compacted with split-die and split-punch arrangements (Olivetti process).

Compaction pressures between 400 and 600 MPa are applied for ferrous structural parts. The range 50 – 800 MPa is used for other materials such as aluminum alloys and high-speed steels. The maximum force of modern presses is in the order of 15 MN, which limits the compaction area of the structural parts to $< 60\,cm^2$.

5.2. Isostatic Pressing, Cold Rolling, and Extrusion

For *cold isostatic pressing*, powder is filled into elastic molds that may have a rigid core or mantle

Figure 6. Uniaxial compaction of metal powder
A) Density distribution in the compacted powder bed when upper punch moves, die and lower punch are fixed (case C); B) Density distribution when upper and lower punch move and die is fixed or with floating die if upper punch moves and lower punch is fixed (cases D, E, F); C) Single action pressing; D) Ejection process; E) Floating die process; F) Withdrawal process

and are sealed and subjected to hydrostatic pressure in an oil bath [77], [78]. Densification of the powders is usually isotropic. Shape retention of the elastic molds is moderate, but improves considerably if rigid cores or mantles are used. The economical pressure range is 30 –700 MPa.

In the wet-bag arrangement the powder is sealed in a flexible envelope made of poly(vinyl chloride) or polyurethane which is completely immersed in the pressure medium. The mold cavity is filled with powder, sealed with the cover plate, pressure is applied and released, the cover plate is raised, the green compact removed, and the cycle repeated. The wet-bag method has a low production rate compared to the dry-bag variant where the envelope (membrane) is permanently sealed into the pressure vessel (Fig. 7). The dry-bag method is mainly used for the production of spark plugs and thin-walled tubes.

Figure 7. Simple dry-bag tool for cold isostatic pressing [77]
a) Pressure vessel; b) Membrane; c) Powder; d) Pressure outlet; e) Core rod; f) Pressure inlet

Advantages of isostatic pressing are

1) Lower pressure required to obtain a given density
2) More homogeneous axial density distribution in the compacts
3) Greater freedom in the shape choice, e.g., for parts with undercuts and thin walls or with large height to diameter ratios
4) Pressing aids can be avoided

Powder rolling and extrusion are methods used to obtain compacts for semifinished products from powders. In *powder rolling* powder is fed from a hopper into the gap of a rolling mill and emerges as a continuous compacted strip or sheet which is then sintered. The sintered green strip is still porous and can be used to produce large stainless-steel filter plates. The sintered strips have to be rolled again to obtain dense filter plates [79]. Powder rolling is economically advantageous for metallurgical refining methods that provide cheap powders which would otherwise have to be transformed into bulk material by melting. The classical example is the rolling of nickel and cobalt powder produced by the Sherrit – Gordon process [80]. An appropriate powder feed system allows rolling of bimetallic strips.

*Cold extrusion of powders*plastified with a high binder content is used for the production of hardmetal parts with high length to diameter ratios [81]. The plastic binder components must be carefully removed prior to sintering.

5.3. Pouring, Preforming, and Injection Molding

Shapes of filters or electrodes for cardiac pacemakers are manufactured by pouring powder into molds, density may be increased by vibration and subsequent sintering. For slip casting aqueous metal powder suspensions are filled into plaster molds [82]. The suspensions are dehydrated via the plaster capillaries to leave a shell of metal powder covering the mold walls. Slip casting is more popular for shaping ceramics.

Preforming requires presintering of poured or slightly compacted powders which are subsequently machined into parts of different geometry. It is frequently used in the hardmetal industry if shaping is otherwise impossible or if a limited number of parts are required (production of a compaction tool set uneconomical).

Plastified powder – binder mixtures are extensively used for powder injection molding, a process commonly employed for shaping thermoplastics. The process allows the forming of complex shapes such as turbine blades or integral turbochargers [8], [9].

High-density compacts are manufactured by high-speed, high-energy compaction methods which apply high local pressures ($< 10^5$ MPa) for short time intervals ($10^{-3} - 10^{-6}$ s) initiated for example by the ignition of explosives [83].

6. Sintering

6.1. The Sintering Process

Sintering occurs when a system of loose or compacted powders is subjected to heat treatment below the melting temperature of all its constituents (solid-state sintering) or of the major constituents (liquid-phase sintering). Solid-state sintering starts when solid contacts between the particles are formed and/or enlarged. This process is driven by a reduction of the net surface energies of the solid – vapor and solid – solid interfaces. Shrinkage (porosity decrease) may occur with a simultaneous decrease or increase of the average pore size and is driven by the same driving force. Porosity reduction means that an increasing fraction of solid material is found in each unit volume cell as a result of rearrangement and/or shape change of the particles (Fig. 8) [84], [85].

Figure 8. Shrinkage by rearrangement and center approach (shape change) during sintering

6.1.1. Solid-State Sintering

Figure 9 shows the densification of compacts from copper powder during isothermal sintering at 700 – 1000 °C. The shrinkage rate declines continuously during isothermal sintering, indicating a decreasing rate of material transport responsible for changes in the arrangement or shape of the particles. The reduced transport rates are due to lower driving forces, longer transport paths, and the fact that increasing volumes have to be transported to produce equal macroscopic density changes. The shrinkage rate for materials of equal density increases with decreasing particle size and increasing temperature, the transport process is thermally activated [84].

Figure 9. Densification of copper powder compacts (150 MPa, average particle size 45 µm) during sintering at different temperatures

A grain comprises a single crystal with a long-range periodic lattice order. If two such grains come together, the lattices point in different directions and form a grain boundary. A particle may consist of one or many grains.

Metallographic sections of the copper compacts at densities of 70, 86, and 96 % of the theoretical density (i.e., 30, 24, and 4 vol % porosity, respectively) characterize three subsequent stages of different pore arrangement during sintering (Fig. 10). In stage 1, solid material bridges form in the necks between individual particles. The reduction in porosity is modest until the size of necks is approximately one-third of the particle diameter [86]. Grain growth to sizes above that of the initial powder is usually suppressed. If a loose arrangement of spheres is considered (initial density 58 – 68 % [87]) the transition to stage 2 occurs at densities of ca. 75 % of the theoretical. Individual particles can no longer be distinguished and pore channels are situated along triple junctions of adjacent grains. Stage 2 is characterized by rapid shrinkage and slow grain growth [88], [89]. Stage 3 starts at densities between 91 and 95 %; the interconnected pore channels become unstable, forming isolated pores which lie at the grain boundaries or inside the grains [90], [91]. The open porosity is thus transformed into a closed porosity. During the final stage of sintering both slow densification (pore shrinkage) and fast coarsening (pore coarsening and grain coarsening) occur. During the production of parts with inherent porosity and structural parts, sintering is terminated during stage 1 or early in stage 2. Due to the high initial (green) densities of structural parts, the transi-tion from stage 1 to stage 2 occurs at densities of 86 – 92 %. Sintering of structural parts is thus usually restricted to stage 1, i.e., sintering is terminated after the formation of sintered contacts between adjacent particles without pronounced shrinkage.

Sintering theory provides a helpful general picture of the material transport processes that occur during sintering. The influence of parameters such as particle size, initial density (green density), temperature, and time has to be explained to allow control of dimensional and microstructural development during sintering. Sintering involves many particles, as a result theory cannot explain all details, especially in more complex systems, nor can it provide accurate quantitative predictions.

During solid-state sintering of amorphous material [92], center approach occurs by viscous flow in the neck region. During solid-state sintering of crystalline particles, center approach occurs when vacancies that emanate from the surface of the neck regions (source) are eliminated at the grain boundaries in the particle necks (sinks) [93]. The vacancy flux and the equivalent counter flux of atoms are driven by stress gradients in the contact areas that result from the surface curvatures in the neck regions. Figure 11 shows the five transport paths for the atoms (as counter flux to the flux of vacancies): grain boundary diffusion, bulk diffusion from

Figure 10. Stages of solid-state sintering

the neck to the grain boundary, bulk diffusion from distant surfaces to the neck surface, surface diffusion, and evaporation and recondensation. All fluxes lead to neck growth, but only grain boundary diffusion (Gb) and bulk diffusion from the neck to the grain boundary (V_1) are involved in the center approach of the particles and macroscopic shrinkage.

Figure 11. Two-particle model of solid-state sintering
ER = evaporation and recondensation; Gb = grain boundary diffusion; S = surface diffusion; V_1 = bulk diffusion from the grain boundary to the neck; V_2 = bulk diffusion from distant surfaces to the neck surface
a = radius of the initial sphere; h_0 and h = initial and actual distances between centres of the initial spheres, respectively; x = neck diameter; ϱ = main radius of curvature of the neck surface which is assumed to be part of a circle

Equations describing the neck size, x/a, and the relative shrinkage, $\Delta h/a$ (see Fig. 11) during initial sintering (stage 1) are of the general form [84]

$$(x/a)^n = Ct/a^m \tag{4}$$

and

$$(\Delta h/a)^{n/2} = (Ct) / (2^n a^m) \tag{5}$$

The parameters n, m, and C for the different transport processes are given in Table 2 [94].

The models for stage 2 assume pores either to be situated as continuous constant diameter channels along the triple junctions of an arrangement of grains of space-filling Kelvin bodies or as continuous channels with varying diameter along the triple junctions of irregular grains [98]. The equations are similar to those for stage 1 (Kelvin bodies are regular bodies with flat surfaces which can fill space perfectly in a regular arrangement, e.g., a cube but not an octahedron).

A similar approach was used for stage 3, when isolated pores of uniform size were assumed to be present at all corners of the space-filling polyhedrons (grains). This approach becomes invalid, however, when pores separate from grain boundaries.

During grain growth in stage 3, pores remain at the boundaries or become separated and "trapped" inside the grains (Fig. 12). Trapped pores usually shrink at much lower rates than the pores at the grain boundaries, since bulk diffusivity is much smaller than grain boundary diffusivity [90], [91], [99].

On the basis of the sintering equations described above, Ashby developed a graphical representation of the sintering behavior of powders [100], [101]. These sintering diagrams plot the relative neck radius (x/a) or the relative density as a function of temperature and time. Areas

Table 2. Parameters for initial sintering (stage 1) of spherical particles for Equations (4) and (5)

Transport	Measured		Plausible			Reference
mechanism	n	m	n	m	C	
Viscous flow	2	1	2	1	$3\gamma_{SV}/2\eta$	[95]
Evaporation and condensation (ER)	3 – 7	2 – 4	3	2	$2.4\varepsilon Z$	[96]
Grain boundary diffusion (Gb)	6	4	6	4	$48 D_g \delta Z$	[97]

Surface diffusion (S)	3 – 7	2 – 4	7	4	$23 D_s \cdot (\Omega k/R)^{1/3} Z$	[97]

δ = effective thickness of the grain boundary; D_g, D_s and D_v = grain boundary, surface, and bulk diffusion coefficients, respectively; ε = reaction rate constant; γ_{SV} = specific surface energy; η = viscosity; k = Boltzmann constant; R = gas constant; T = absolute temperature; Ω = molar volume; $Z = \gamma_{sv}\ \Omega/RT$.

are identified in which a single transport mechanism has a dominating effect on the neck growth rate. The sintering diagrams are valuable tools for initial assessment of the sintering conditions required for a particular material of known composition and grain size. The accuracy of the sintering diagrams is, however, limited by the accuracy of the models from which the equations are obtained and the diffusion and interface energy data [100].

Figure 12. Microstructure showing trapped pores (e.g.∗) and pore/grain boundary separation (→) during final stage (3) sintering of tungsten containing 0.15 wt % nickel at 1400 °C for 3 h

Shrinkage and grain growth of materials as well as dimensional changes and homogenization of metallic structural parts are often manipulated by using sintering additives. Additives, unlike impurities, are intentionally added to the sintering systems. The usual impurity level is below 1000 ppm [1], whereas the amount of additive may vary from 0.1 to 10 wt %. Some additives are present as solid phases, as solid solutions with the host metals, or as segregates at the interfaces of the host metals. Other additives form liquid phases which often penetrate as thin films between the particles (which consist of one or more grains) and grains of the host powder [102]. Additives are frequently used to accelerate shrinkage (e.g., Ni for W or MgO for Al_2O_3), they enhance one of the diffusion mechanisms leading to shrinkage (e.g., grain boundary diffusivity) or suppress mechanisms which lower the driving force (e.g., surface diffusion) [103–107].

Densification, dimensional control, and homogenization can also be influenced by additives which are present as a second solid phase. These additives may provide a fast diffusion path for the host atoms. The additive may also form inclusions or obstacles which retard densification and grain growth. The broad variety of chemical interactions between the solid phases has a complex influence on densification and dimensional control.

6.1.2. Liquid-Phase Sintering

Densification during liquid-phase sintering is also based on rearrangement and shape change of the solid constituent particles (see Fig. 8) [84], [85]. The driving force for both liquid- and solid-state sintering is based on a decrease in energy connected with the changes in the areas of the liquid – vapor, liquid – solid, and solid – vapor interfaces. In liquid-phase sintering melt may originate from low-melting particles or areas which have low-melting point compositions resulting from diffusion during heating. With good wetting, the liquid phase is drawn into particle

necks and small pores by capillary forces [108–111]. As a reaction to the capillary forces, solid particles rearrange if they have sufficient mobility. This rearrangement is a prerequisite for effective densification throughout the sintering process even during later stages when, for example, the rates of particle shape change also limit the rearrangement rate.

Rearrangement may be primary or secondary. In primary rearrangement, the rate is controlled by mechanical movements produced by capillary forces. In secondary rearrangement, the rate is controlled by dissolution and reprecipitation [112]. Shrinkage resulting from the shape change of the solid constituents always involves dissolution – reprecipitation.

During liquid-phase sintering the initial irregular or spherical shape of the single crystal grains becomes polyhedral. Contact flattening is assumed to be a responsible mechanism for this shape change and the shrinkage that occurs during liquid-phase sintering [113]. Contact flattening is a dissolution – precipitation process which is driven by the high chemical potential of the solid matter in the contact area. A thin residual liquid film is assumed to exist between the particles. Under the assumption of local equilibrium the solid phase dissolves at the contact region of two adjacent particles. In the liquid film material is transported out of the contact area in a diffusion- or reaction-controlled manner and reprecipitated at sites of solid matter outside the contact region. The removal of material from the contact area leads to contact flattening. In contrast to the contact flattening theory the shape accomodation theory assumes shape accommodation and shrinkage to be closely connected to grain growth [114], [115]. Shrinkage is described as secondary rearrangement (controlled by a solution – precipitation process) which occurs when small particles dissolve, making way for the movement of larger particles.

Grain growth (coarsening) during liquid-phase sintering of PM materials determines their densification rate and their properties after processing. In many systems grain coarsening follows the relation

$$G_m^n = (G_{m0}^n + kt)^{1/n} \tag{6}$$

which indicates diffusion- or reaction-controlled Ostwald ripening ($n = 3$ or 2, respectively) as the rate-controlling step [116], [117] where G_m and G_{m0} are the actual and the initial grain size, respectively, k is a growth constant, and t is the growth time.

The penetration of melt into grain boundaries is a further important dissolution–reprecipitation mechanism for liquid-phase sintering. Grain boundary penetration leads to skeleton disintegration, but also to contact dilatation, particle dilatation, and particle disintegration. Other important consequences are boundary alloying and liquid film migration [112], [118–120]. Dimensional changes during liquid-phase sintering due to grain boundary penetration are of commercial interest for structural parts. For example, in high-green-density compacts from iron and copper powder blends, copper-rich melt penetrates into the contact regions between adjacent iron particles and along grain boundaries. Additional melt in prior contact areas and at prior grain boundaries inside the iron particles causes contact and particle dilatation leading to macroscopic swelling [121].

6.2. Sintering Furnaces and Atmospheres

Sintering temperatures depend on the alloy type and whether solid-state or liquid-phase sintering is anticipated. Common sintering temperatures are ca. 600 °C for aluminum alloys, 750 °C for copper bronzes, 900 °C for brass, 1120 – 1200 °C for copper, nickel, and Cu – Ni – Mo distalloy steels, 1200 – 1280 °C for high-alloyed steels, 1400 °C for hardmetals and heavy-metal alloys, 1600 – 2500 °C for refractory metals such as molybdenum and tungsten [122]. The most frequently used sintering furnaces are of the belt, walking beam, or batch type (Fig. 13).

Belt Furnaces. Mesh belt furnaces (Fig. 13 A) are used at temperatures up to 1150 °C. The compacts to be sintered are put directly on conveyor belts made of stainless steel nets or are packed into boxes which are transported by the belt through the sintering furnace at constant speed. The nickel – chromium heating elements allow annealing in protective gas which burns as a flame curtain at the entrance and the exit of the furnace. The initial preheating (dewaxing)

Figure 13. Section through a conveyor belt furnace (A) and a walking beam furnace (B)
a) Sintering tray; b) Conveyor belt; c) Muffle; d) Walking beam; e) Atmosphere lock

zone is operated at 600 – 800 °C; binders, pressing aids, and humidity are decomposed and removed from the parts. The central sintering zone is followed by a cooling zone.

Endo- and exogas are most frequently used as protective gas, they are both prereacted mixtures of methane and air containing carbon monoxide, carbon dioxide, hydrogen, and nitrogen. Exogas has a high partial pressure of carbon dioxide and reduces the oxides of iron, nickel, and copper. Endogas has a low partial pressure of carbon dioxide. The CO/CO_2 ratio determines the equilibrium carbon concentration in sintered PM steels. Exogas stabilizes a high, endogas a higher carbon concentration [123]. Hydrogen or catalytically decomposed ammonia is used less frequently.

Walking beam furnaces (Fig. 13 B) are used at temperatures up to 1350 °C and have molybdenum heating elements. Boats or trays are conveyed and periodically lifted, advanced a short distance, and then settled back on a ceramic ledge. Protective gas flow is controlled by sluices. In addition to the gases described for mesh belt furnaces, nitrogen is also used.

Batch sintering furnaces are used for hydrogen, nitrogen, or vacuum sintering. Hydrogen is used for sintering of tungsten, molybdenum, and iron of high purity, nitrogen is used for aluminum alloys. Vacuum sintering is applied for high-alloyed steel, hardmetals, magnets, and materials containing alloying elements sensitive to oxidation (e.g., chromium and aluminum). Extremely high vacuum is required for sintering niobium and tantalum. Sintering temperatures above 1500 °C are obtained with molybdenum, tungsten, or tantalum heating elements.

7. Pressing and Shaping at Elevated Temperature

Direct consolidation at elevated temperature by processes such as hot pressing, hot isostatic pressing, sinter forging, or hot extrusion results in simultaneous shaping and consolidation. Powder, precompacts, or porous presin-

tered parts are mostly consolidated to full-density products.

Figure 14. Pressure vessel for hot isostatic compaction a) Isolating lid; b) Isolating mantle; c) Furnace; d) Wire wound pressure vessel; e) Part to be pressed; f) Vessel lid

7.1. Hot Pressing and Hot Isostatic Pressing

Hot pressing is applied for simple geometries such as small cylinders or plates. The pressing tool sets are mostly simplified analogs of those used at ambient temperature and are generally built from graphite, in rare cases from stainless steel, refractory metals, or ceramics. Conventional compaction pressures are between 20 and 50 MPa at temperatures of 600 – 2100 °C. The main application of hot pressing is for cutting and grinding composite tools of diamonds embedded in cobalt or other metal matrices [124].

Hot isostatic pressing (*HIP*) has a broader range of applications than hot pressing [125], [126]. The parts are consolidated and densified in pressure vessels at elevated temperature (up to 2300 °C) and elevated pressure of helium or argon (50 – 200 MPa) (Fig. 14). Parts with open porosity require prior encapsulation in steel or glass containers. Open porosity may be defined as sintering stage 2 porosity which involves continuous channels connecting the interior of the part with the surrounding gas. Powders or precompacts are filled into the containers, which are usually evacuated at elevated temperature before sealing. The heating furnace is placed inside the pressure vessel and well isolated against heat transmission to the pressure vessel walls.

Homogeneous isotropic densification yields final part geometries of good accuracy (near net shape method) which only require minor final machining and show an excellent (low) ratio of initial to final weight. Large parts made of stainless steel (Fig. 4) or other high-value alloys (e.g., superalloys or Ti alloys) are important applications. A superior economy of HIP is realized if encapsulation is not required (i.e., in parts with closed porosity or closed porous defects).

Sintering to closed porosity and immediate complete densification to full density by HIP in one furnace and a single processing cycle (sinter – HIP) is frequently used in hardmetal manufacture. The additional HIP treatment allows the use of cheaper, less well defined initial powder or the production of extremely fine-grained hardmetal materials [19]. Sinter – HIP furnaces work at < 10 MPa and are therefore much larger and cheaper than full pressure (≤ 200 MPa) HIP furnaces [126]. HIP can also be used for defect (porous) healing in sintered materials [127] or, for example, in superalloy turbine parts after a prolonged lifetime [125].

Densification during hot pressing and hot isostatic pressing is mainly controlled by power-law creep and diffusion processes similar to those occurring during sintering. Densification kinetics are described satisfactorily by approaches which include consideration of rate changes caused by grain growth at high densities [128–130]. The micromechanical relations are the basis of the calculation routines for HIP diagrams. They yield predictions of the density of the powder compact depending on the pressing parameter and the initial particle size [128].

More precise predictions of densification and shape stability are obtained by finite element calculations [131], [132].

7.2. Sinter Forging and Other Methods

In some cases the required geometry and mechanical properties of parts make *sinter forging* (powder forging) an economic alternative to other production methods. Presintered, reheated

parts of exact mass and dimensions can be forged in closed dies without flash to a precision not obtained by conventional forging. Compared to conventionally forged parts, sinter-forged connecting rods show superior reliability and fatigue strength due to their improved surface quality and the absence of chemical inhomogeneities or large nonmetallic inclusions [133]. In addition, the properties of sinter forged products are essentially isotropic [134]. Prealloyed Mn – Cr and Mn – Cr – Mo steel powders are usually used for sinter forging of ferrous parts. Aluminum- and titanium-based alloy powders and superalloy powder are increasingly used for superplastic sinter forging.

Hot extrusion of powders provides profiled, dense rods at temperatures that are much lower than those required for densification by hot isostatic pressing. Most powders are encapsulated in a metal container and cold isostatically precompacted in a similar manner to the hot isostatic pressing route. Seamless stainless steel tubes with chemical homogeneities superior to cast and wrought materials are manufactured by this procedure (Asea – Nyby process) [135]. Hot extrusion became very popular in the late 1980s for full densification of metal – matrix composites which did not sinter to full or closed porosity without additional external pressure [136]. The large contribution of shear strains to densification and particle deformation results in the advantageous destruction of reaction products at the surface of the powders. Sometimes this makes hot extrusion preferable to hot isostatic pressing, despite the fact that hot-extruded bars show highly anisotropic material properties. Similar anisotropic properties are obtained after *hot rolling* of encapsulated powders.

Deformation during powder forging, hot extrusion, and hot rolling is rapid and depends mainly on the yield strength of the material which decreases with temperature and on dynamic recrystallization or recovery.

8. Structural Parts

8.1. Structural Ferrous Parts

PM structural parts are produced from metal powder (ferrous alloys, to a smaller extent also aluminum alloys and copper alloys) by compacting and sintering to closely controlled dimensions.

Powder metallurgy is often economically advantageous over other methods for the production of complex-shaped structural ferrous parts. The mechanical properties of PM structural ferrous parts are adequate for many applications but usually slightly inferior to the properties of machined parts, mainly due to the residual porosity [137]. Main customers are the automotive, electrical, and general machinery industries.

Structural parts with densities between 78 and 92 % of theoretical density are obtained by the single press – sinter process. Densities of 92 –95.5 % require a double-sinter process comprising uniaxial cold pressing, sintering, cold repressing, and resintering. Densities > 95.5 % are achieved by powder forging (see Section 7.2) [6].

Data on the influence of the porosity on the mechanical properties of pressed and sintered PM structural parts are given in [138], [139]. Figure 15 shows a compilation of data for iron [140].

Figure 15. Mechanical properties of ferrous PM material as a function of the density [140]
σ_u = ultimate tensile strength; σ_{bf} = bending fatigue strength; ε_u = ultimate fracture elongation; a_t = fracture toughness

In general, the mechanical properties increase with increasing density. The pore shape determines the extent of their stress intensifica-

tion which particularly affects elongation and impact strength [141], [142]. Tensile strength and hardness show an almost linear increase. The strength of compacts from straight iron powder is limited. Higher strength PM structural parts are produced from powder mixtures of iron and alloying elements, the most important being graphite, copper, nickel, molybdenum, and phosphorus powder [143]. In special cases (e.g., for sinter forging), powders mainly prealloyed with nickel, manganese, molybdenum, and nickel are blended with graphite [144].

8.1.1. Low-Alloyed Steels

Table 3 lists the compositions and mechanical properties of typical ferrous steels densified to three density ranges [139]. Alloying elements of high oxygen affinity such as vanadium, manganese, and chromium are avoided in powder blends to be sintered but common for prealloyed powders to be powder forged. The use of alloying elements (e.g., Cu and P) which lead to grain boundary embrittlement and detrimental problems during warm forming in conventional steels is possible since no further forming step (except coining at room temperature) is required after sintering to obtain the final parts.

Copper additions of 1.5 – 5 wt % provided classical PM steels which required only minor control of the carbon potential of the sintering atmosphere. Iron – copper alloys are sintered at 1120 °C, i.e., above the melting point of copper, which leads to swelling of the compacts by melt penetration into particle contacts and grain boundaries (Section 6.1.2). The swelling may compensate the usual shrinkage during sintering of powder compacts [121], [145]. Copper acts as a solid solution and precipitation hardener [146], [147]. Nickel additions improve the toughness and weldability of ferrous steels.

Fe/Cu/C and Fe/Cu/Ni/C steels are stronger than low-carbon steels but require precise carbon control during sintering. Fe/P PM steels are characterized by a good combination of strength and toughness due to the formation of rounded pores during sintering. The major disadvantage of phosphorus-alloyed steels is their extensive shrinkage due to the formation of a eutectic liquid phase between the Fe_3C alloy powder and the iron particles. In addition, the presence of phosphorus in iron stabilizes the ferrite phase which shows a much higher bulk diffusion coefficient than the austenite.

FeCuNiMoC alloys are mainly manufactured from distalloy powder. Molybdenum suppresses the local enrichment of nickel which would lead to soft spots in the sintered material caused by retention of austenite after cooling.

8.1.2. High-Alloyed Steels

Parts made of austenitic and martensitic stainless steel are produced from prealloyed powders which are usually obtained by water atomization and less frequently by nitrogen gas atomization. The compositions are close to those of cast and wrought stainless steels (e.g., 316 L with the composition Fe13Ni17Cr2.1Mo0.7Si [148]). The high content of alloying elements re-sults in powders with low compressibilities which require lubricants to obtain sufficiently high green densities. These powders have to be dewaxed carefully before sintering to avoid the pickup of carbon. Sintering at 1120 °C in vacuum or hydrogen provides stainless steel parts of higher ductility but lower strength than sintering in a nitrogen atmosphere [149]. Small amounts of free carbon may be added to allow carbon monoxide formation during sintering thereby reducing the oxygen pickup. Austenitic stainless steels sintered in a vacuum to densities of 6.5 g/cm^3 show an ultimate tensile strength of 300 MPa and ultimate fracture elongations of 2 – 4 %. Martensitic stainless steels possess strength values > 450 MPa and negligible elongation (< 1 %). The open porosity of PM stainless steel structural parts has a disadvantageous effect on corrosion behavior, they are therefore often impregnated and sealed with resins or waxes.

The applications for stainless steel PM parts have been extended by the *Asea – Nyby process* for seamless tubes [135], [150] and the manufacturing of small parts with complex shapes by *powder injection molding* (e.g., for orthodontic purposes [151]).

High-speed tool steels are hard, tough, wear-resistant, high-alloyed ferrous materials which contain up to 20 wt % of tungsten, molybdenum, chromium, vanadium, cobalt, and sufficient carbon to form high-volume contents of

Table 3. Composition (in wt %) and mechanical properties of typical ferrous PM steels densified to three density ranges

Composition	Process	$\varrho = 6.4 - 6.8$ g/cm^3		$\varrho = 6.8 - 7.2$ g/cm^3		$\varrho = 7.2$ g/cm^3

ϱ = density; σ_u = ultimate tensile strength; ε_u = ultimate fracture elongation

tungsten, molybdenum, chromium, and vanadium carbides [152]. Cast high-speed tool steels develop coarse, inhomogeneously distributed carbide networks which have to be homogenized by thermomechanical treatment. Gas or water atomization (with protective N_2 atmosphere) yields powders with homogeneous microstructures and very fine carbide precipitates. The fine microstructures are retained during consolidation. The *ASEA – Stora process* involves inert gas atomization of high-speed tool-steel powder which is filled into steel containers and cold isostatically pressed [150]. After hot degassing at 450 °C and sealing, hot isostatic pressing at 100 MPa and 1100 °C yields dense billets weighing up to 1000 kg. This technique avoids carbide segregation and yields billets with a uniform macro- and microstructure comprising evenly sized and distributed carbide particles with a fine, uniform grain size. Shaped parts are produced from the billets by machining.

Conventional uniaxial or isostatic pressing and vacuum sintering of water-atomized high-speed steel powder is used in the *Powdrex process* to manufacture high-speed tool-steel parts. The sintering temperature has to be kept to within a few degrees of 1240 °C, and the C/O_2 level of the compact must be carefully controlled to allow sintering to full density with a limited amount of liquid phase [153]. At higher temperatures coarse carbides form, at lower temperatures residual porosity is maintained. This net-shape sintering process gives superior material and economy compared to the cast and wrought route [154]. PM steels with high wear resistance are based on high contents of titanium carbide [155].

8.1.3. Secondary Operations

Some secondary operations are applied to both PM and non-PM parts, e.g., hardening by heat treatment, joining, and surface modification. Particular to sintered porous parts are coining operations and pore filling by reaction with steam or by infiltration with metals or polymers.

When ferrous PM structural parts are subjected to quench *hardening* the lower heat conductivity of the porous material must be considered. Materials with open porosity are sensitive to corrosion or oxidation and require protective atmospheres and oil instead of water as quenching medium. For case-hardening of parts with closed porosity, carbonizing or nitrocarburizing in high-carbon or carbon – nitrogen atmospheres and subsequent quenching in oil is used. Parts with open porosity require impregnation (e.g., with waterglass) or prior surface coating to avoid hardening embrittlement and severe dimensional changes in the interior of the parts. Plasma nitriding is increasingly preferred to gas and salt bath nitriding due to the defined high-quality surface layers formed [156].

Almost 90 % of the ferrous structural parts are coined after sintering. *Coining* improves the accuracy of dimensions and shape, the finish, and the mechanical strength of the surface ar-

eas. Threads and holes are machined perpendicular to the pressing direction. Machining is also applied to those surface areas which require exact geometry and superior surface finish [157], [158].

*Surface coating and modification*are used to improve corrosion or wear resistance. Galvanic precipitation, chemical or physical vapor deposition (CVD or PVD), and steam treatment are commonly employed. The first two methods require closed porosity or impregnation of the open porosity with waterglass, waxes, or resins prior to coating. Nickel, copper, chromium, and zinc are mainly deposited galvanically, whereas hard layers of nitrides or carbides are formed by CVD or PVD. During steam treatment at 450 – 570 °C, iron(III) oxide forms in the pores and adheres to the ferrous material, providing gastight closure of the initially open pore space. Self-lubricating bearings are manufactured by impregnating highly porous ferrous parts with lubricants (Chap. 10).

8.2. Copper and Copper Alloys

PM structural parts from pure copper are used for applications where good electrical and thermal conductivity are important [159]. High-purity electrolytic or gas-atomized copper powder is compacted to densities up to 90 %. Higher green densities are possible but outgassing becomes impossible due to the mainly closed porosity which leads to swelling of the copper compacts. (Outgassing is the decomposition of residual impurities or binders into volatile products which leave the compact through the open porosity, usually at slightly elevated temperature and under a partial vacuum.) Parts with a higher final density are obtained by outgassing and sintering compacts with a low green density that have previously been repressed and resintered after initial sintering. At 98 % of the theoretical density ca. 97 % of the International Annealed Copper Standard (IACS, standard electrical conductivity, → Copper Alloys, Chap. 1.) is maintained at an ultimate tensile strength of 200 MPa and at ultimate fracture elongations ≥ 30 %[160].

PM bronze structural parts are generally produced from mixtures of copper and tin powder by methods very similar to those used for self-lubricating bronze bearings (see Chap. 10). Structural parts from brass, leaded brass, and nickel silver (Cu18Ni17Zn) are produced from gas-atomized (usually air) powders [159]. Materials with higher lead and zinc contents require careful control of the lead and zinc evaporation rates during sintering at elevated temperature.

8.3. Aluminum and Aluminum Alloys

See also → Aluminum Alloys, Chap. 4.5.

PM aluminum alloys are successfully manufactured from mixtures of air-atomized aluminum powder with lubricants (e.g., zinc stearate) and up to 8 wt % of alloying elements (e.g., Cu, Mg, and Si). High green densities of 90 – 95 % are obtained with moderate compaction pressures of 200 – 400 MPa due to the low yield strength of the aluminum powders. Lubrication is required to avoid galling and seizing during pressing. The alloying additions form a liquid phase which penetrates below the thin oxide layers coating the surfaces of the aluminum powder particles. Similar to wrought alloys, the PM alloys may be strengthened by precipitation hardening and surface treated by chemical polishing, anodizing, and coloring. Depending on the thermal treatment an ultimate tensile strength between 120 and 300 MPa is achieved at low ultimate fracture elongations (between 4 and 1 %) [137].

9. High-Performance Materials

9.1. High-Melting Metals and Alloys

See also → High-Temperature Materials, Chap. 8.

The refractory metals (i.e., W, Mo, Ta, Nb, Re, Hf, Os, Ru, and Ir) possess melting temperatures above 2000 °C and have a low vapor pressure, low thermal expansion coefficient, high elastic modulus, high recrystallization temperature, and a remarkably high temperature strength [161]. Their mechanical properties sensitively depend on their microstructure (i.e., grain size, dislocation density), and on substitutional and interstitial impurities. Recrystallized tungsten and molybdenum are embrittled by oxygen, sulfur, and phosphorus impurities that segregate at the grain boundaries as atoms or as oxides, for

example. To avoid spalling and splitting as a result of brittle grain boundary fracture, plastic forming of tungsten and molybdenum requires elevated temperature. Molybdenum, tungsten, and rhenium are mainly processed in a hydrogen atmosphere. During application they require protective atmospheres or a vacuum.

In contrast to tungsten and molybdenum, tantalum and niobium dissolve considerable amounts of oxygen at elevated temperature and are less susceptible to grain boundary embrittlement. Tantalum and niobium are usually processed in a vacuum and also require a vacuum or a protective atmosphere during application at elevated temperature. Osmium, ruthenium, and iridium can be used in air [161].

The Coolidge process was invented in 1908 and provided fine-grained tungsten and molybdenum products. Uniaxially (in split dies) or isostatically compacted bars of molybdenum or tungsten powders were presintered at 1200 °C to improve their strength for easier handling. In a subsequent sintering treatment densities > 90 % were reached by passing a low-voltage, high-amperage current through the presintered bars, which reached temperatures > 3000 °C for up to 30 min [162].

In modern production lines, the compacted bars are usually subjected to indirect sintering in tungsten furnaces under a hydrogen atmosphere at > 2000 °C to give densities of 92 – 95 % [163]. Tantalum and niobium are usually sintered by the Coolidge method under vacuum.

The sintered refractory metals are brittle, with porosities up to 10 %. Complete densification and increased toughness are obtained by a multistep thermomechanical treatment. A typicals sequence for manufacturing tungsten wires for incandescent lamps is rolling of the sintered rods at 1600 °C, followed by swaging at 1500 °C. Temperatures are lowered to 900 °C with progressing deformation. The swaged bars are drawn into wires in cemented carbide and diamond dies. The drawing temperatures are gradually lowered from 800 to 400 °C [163]. Tungsten wires for lamps contain the so-called KAS dopant (a combination of K_2O, Al_2O_3, and SiO_2). The dopant is blended with WO_3 before reduction to tungsten powder under hydrogen. The KAS dopant forms strings of fine bubbles parallel to the wire-drawing direction during the final processing steps. Due to the presence of the bubble rows the wires develop a recrystallized structure of elongated grains. Undoped tungsten or molybdenum wires develop an equiaxial recrystallization structure with a considerably reduced lifetime compared to KAS-doped materials. The addition of ThO_2 and KAS simultaneously improves the thermal emissivity of electrons and is mainly used for electronic tungsten or molybdenum materials.

Alloys based on solid solutions of tungsten or molybdenum with rhenium have improved ductility and high-temperature strength compared to the unalloyed materials. They are only rarely used, however, due to the high cost of rhenium metal [80]. The technically most important molybdenum alloy is TZM which contains 0.5 wt % Ti, 0.07 wt % Zr and 0.05 wt % C. See also → Molybdenum, Chap. 4.5.

Liquid-phase sintered tungsten alloys with 2 – 6 wt % Ni, 2 – 4 wt % Cu, and/or 1 – 4 wt % Fe have found major application as high-density shells for penetrators in artillery bullets. At densities of 17.5 – 18.5 g/cm^3 their ultimate tensile strength exceeds 1200 MPa at fracture strains between 10 and 30 % [164].

Niobium and tantalum products are mainly used as sheets and wires for the electronic and chemical industry [80]. A major application of tantalum powder as a substrate for capacitors is described in Chapter 10.

9.2. Light Alloys

9.2.1. High-Performance Aluminum Alloys

For a complete description of aluminum alloys, see → Aluminum Alloys.

High-performance PM aluminum alloys provide improved high-temperature creep resistance, corrosion resistance, and a high specific stiffness. These properties are obtained by rapid solidification, oxide- or carbide-dispersion hardening, and particle reinforcement [165], [166].

Rapid solidification is typically performed by atomization, melt spinning, or planar-flow casting; it mainly provides prealloyed powders with fine microstructures and solid solutions. The rapidly solidified ribbons or sheets obtained after melt spinning or planar flow casting have to be milled to fine powders before processing. Processing usually involves degassing, cold

isostatic compaction, encapsulation, degassing, hot isostatic pressing, decapsulation, and extrusion. An alternative to cold isostatic compaction, encapsulation, degassing, hot isostatic pressing, and decapsulation is vacuum hot pressing without encapsulation.

Rapidly solidified aluminum alloys can be classified into high-strength, high-temperature, and lightweight alloys [167].

High-Strength Alloys. The compositions of the high-strength aluminum alloys are generally identical to those of conventional ingot cast and wrought alloys. See also → High-Temperature Materials, Chap. 4. The strength is slightly improved by the refinement of the microstructure due to rapid solidification and the addition of alloying elements that form finely dispersed precipitates. Typical compositions are cast (ingot metallurgy) IM 2618 and powder metallurgy PM 2618 with Al6Cu0.5Mg1Fe1Ni; ultimate tensile strength values reach 600 MPa in the aged conditions. Other efforts have concentrated on the 7000 series with main alloying elements zinc, copper, and magnesium and small additions of cobalt, nickel, zirconium, or molybdenum [168]. The development of low-density aluminum alloys, including "light" alloying elements (e.g., Li and Be), was dampened by successful IM Al – Li alloy developments [166].

High-Temperature Alloys. See also → High-Temperature Materials, Chap. 4. Excellent mechanical properties (especially thermal stability, creep strength, corrosion resistance, and fatigue strength) have been demonstrated for rapidly solidified aluminum – transition metal alloys. These high-temperature alloys have a high-volume content of precipitates with an improved aging behavior, this requires a low diffusion coefficient and a low solubility of the precipitate-forming alloying elements in the aluminum matrix. The alloying element iron satisfies the conditions of low solubility and diffusion coefficient and is used at levels between 8 and 12 wt % together with up to 4 wt % of a ternary additive (e.g., V, Mo, or Ce). To achieve a sufficient volume fraction of precipitates in the matrix, segregation-free material with extended solid solutions is solidified by argon atomization [169]. Compared to conventional high-temperature aluminum alloys creep resistance is increased by ca. 100 K in an Al – 8 Fe – 2 Mo PM alloy [165]. A second series of high-temperature aluminum alloys receiving attention comprises those based on the Al – Cr system [170].

Aluminum alloys strengthened with dispersoids (very fine inert particles, e.g., oxides, carbides) are manufactured by high-energy milling of aluminum powder blends with dispersoid precursors in attrition or planetary mills [171], [172]. More recently aluminum alloys containing Al_4C_3 and Al_2O_3 dispersoids have been commercialized. Mixtures of aluminum, soot, and an organic milling agent (e.g., 2-propanol) are milled at high energy to obtain homogeneous distribution of the very fine Al_2O_3 particles from fractured powder surfaces and of the graphite particles by continuous fracturing and microforging of the aluminum powder particles (see Section 2.1.2). Reaction of the finely distributed graphite with the aluminum during hot extrusion of the milled powders yields fine Al_4C_3 dispersoids. The thermal stability of the dispersoids makes these dispersoid-strengthened alloys suitable for high-temperature applications.

Lightweight Alloys. Recent years have seen the development of a wide range of lightweight, high-performance aluminum PM composites with a variety of discontinuous reinforcements (e.g., Al_2O_3, B_4C, and in particular SiC). Reinforcement shapes considered for such metal – matrix composites include whiskers, fiber junks, platelets, and spherical particles with mean sizes of 3 – 30 μm. Age-hardenable aluminum alloys of the 2000, 6000, and 7000 series (for applications $< 250\,°C$) as well as rapidly solidified high temperature aluminum alloys (for applications $> 250\,°C$) are used as matrix materials. The composites combine strength values up to 750 MPa with high stiffness [166].

To produce the composites, the reinforcement is subjected to dry or wet blending with the aluminum powder. Mechanical alloying can be used as a processing route for particulate reinforced metal-matrix composites (MMC). Final billet fabrication involves cold compaction, hot outgassing, hot isostatic pressing, vacuum hot pressing, or hot extrusion. At high temperatures (425 – 450 °C) and high strain rates ($0.7\,s^{-1}$) the mechanical alloying composite materials show

extended ductility up to 300 % total elongation due to superplastic behavior [172].

9.2.2. Titanium and Titanium Alloys

See also → Titanium, Titanium Alloys, and Titanium Compounds.

Complex shaped parts from titanium or titanium alloys are manufactured by PM in cases where considerable machining can be avoided and to obtain a low initial to final weight ratio of the finished part. The main user is the aircraft industry (engines and frames). Powders are atomized under vacuum or by the plasma rotating electrode process, outgassed, and filled into containers for hot isostatic pressing. Full density and near net shape processing are required to satisfy the economic criteria. Mechanical properties are comparable to those of thermomechanically manufactured titanium alloys.

The most conventional PM composition is Ti6Al4V. Considerable research and development efforts are being made to exploit rapid solidification techniques for titanium alloys. Preliminary results on a metalloid former Ti8V5Fe1Al powder product obtained by the plasma rotating electrode process indicate that strengths > 1380 MPa can be obtained with ductility levels close to 10 % ultimate fracture elongation [173].

9.2.3. Magnesium and Beryllium

Magnesium is the lightest (density 1.74 g/cm^3), nontoxic structural metal available for engineering applications. Most of the work to date on rapidly solidified magnesium alloys has focused on the improvement of strength levels and corrosion resistance [166], [174].

Practically all fine-grained beryllium is commercially produced by PM. Fine-grained beryllium powders produced by electrolysis of salt baths are vacuum hot pressed or hot isostatically pressed at ≤ 1150 °C. An ultimate tensile strength up to 600 MPa is associated with tensile fracture elongations below 6 %. Beryllium finds applications in the aircraft and space industry for stiff structural constructions, as heat sinks due to its high thermal conductivity and specific heat capacity, and as neutron moderators in nuclear power plants [175]. See also → Beryllium and Beryllium Compounds.

9.3. High-Temperature Nickel and Cobalt Superalloys

See also → Cobalt and Cobalt Compounds, Chap. 6.2. → High-Temperature Materials, Chap. 7.3.

The increase in strength exhibited by nickel- and cobalt-based superalloys is accompanied by a significant decrease in conventional hot workability which increases the overall component cost. Powder metallurgy techniques offer a means of producing these highly alloyed, high-temperature materials with a uniform, homogeneous microstructure that is often superplastic and, therefore, suitable for hot working [176]. Typical compositions of superalloys mainly used for components of military jet engines such as compressor disks, seals, high- and low-pressure turbine disks, and blade retainers are listed in Table 4.

The PM production sequence generally includes hot isostatic pressing of noble-gas-atomized powders into billets of 100 % density at 100 MPa and 1120 – 1200 °C. Consolidated billets are then hot forged slightly above 300 °C in several steps into jet engine parts [177]. Hot isostatically pressed and wrought PM materials show better mechanical properties than cast and wrought material and slightly improved economy due to higher material utilization and fewer forging steps. Still better economy is obtained by near net shape production via hot isostatic pressing alone; the reduction of the initial to final weight ratio is limited by the shape requirements for ultrasonic inspection of the near net shape part before final machining.

Efforts have been made to replace small, internally cooled, directionally-solidified cast blades in aircraft gas turbines by directionally recrystallized blades made of oxygen-dispersion-strengthened (ODS) superalloys (e.g., MA 6000 in Table 4). Mechanical testing indicates that the operating temperatures can be increased by 80 °C at equivalent stress rupture levels of 138 MPa as compared to a directionally solidified MAR – M 247 cast alloy [178].

Table 4. Composition of three PM superalloys (main elements)

Alloy	C	Cr	Mo	W	Ti	Nb	Co	Al	Y_2O_3	Ni

Table 5. Soft and permanent magnetic sintered materials and composites [179]

Material type	Soft magnetic materials	Permanent magnets (energy density, kJ/m^3)	
		Classical	Modern
Metals	Fe, FeP, FeSi	steel (3) AlNiCo (40)	$SmCo_5$ (160)
	NiFe, CoFe	CrCoFe (40)	$Nd_2Fe_{14}B$ (240)
	NiFeMo	$Sm_2(Co, Cu, Fe, Zr)_{17}$ (200)	
Ceramics	MnZn ferrites		Ba ferrites (30)
	NiZn ferrites		Sr ferrites (30)
Composites	resin and inorganically bonded Fe, NiFe, SiFe powder (crystalline, amorphous) cores and parts	resin-bonded AlNiCo	resin-bonded ferrites, $SmCo_5$, $Nd_2Fe_{14}B$
		resin-bonded $Sm_2(Co, Cu, Fe, Zr)_{17}$	

9.4. Magnetic Materials

See also → Magnetic Materials.

The intrinsic magnetization of magnetic materials is determined by the magnetic moments of the atoms and their mode of alignment. A ferromagnetic or ferrimagnetic material is divided up into many small regions (Weiss domains) each of which is fully magnetized, i.e., all the moments within each domain are aligned in the same direction. The demagnetization and, therefore, the hysteresis of nearly all magnetic materials result from the nucleation and displacement of the Bloch walls (boundaries of finite thickness between Weiss domains with different directions of magnetization). Soft magnets and permanent magnets show a small and large hysteresis, respectively. Sintered magnetic materials are listed in Table 5.

Soft Magnets. In soft magnetic materials the motion of the Bloch walls with minimum friction is essential. Therefore the density of the effective centers pinning the Bloch walls should be as low as possible [179]. Pinning centers are most effective if their dimensions are in the order of the Bloch wall thickness, e.g., nonmagnetic inclusions, segregations, grain boundaries, or local lattice distortions (dislocation stress fields).

Soft magnetic PM materials must be single phase, of high purity, and large grain size. Any residual porosity should be present as large pores. In addition the magnetic crystal anisotropy and the product of magnetostriction (volume change associated with magnetization) and internal stresses should be kept low. The advantage of PM materials is based on their homogeneity, near net shaping, and the small amount of scrap. High-quality magnetic alloys for sintered parts may consist of Ni – Fe (36, 50, 80 wt % Ni), Fe – Si (3 wt % Si), Fe – P (0.3 – 0.8 wt % P), and Fe – Co – (V) (49 wt % Co, 2 wt % V) [179]. The porosities are below 5 %. The materials cover a range of coercitivities from 0.02 to 1.5 A/cm and saturation polarization up to 2.3 T.

Permanent Magnets. For permanent magnets high resistance against further change in the direction of magnetization is essential. In the "classical" permanent magnets (e.g., steel or AlNiCo) this was achieved by increasing the density of efficient pinning centers. In modern permanent magnets (e.g., $SmCo_5$) the extremely high magnetic crystal anisotropy constants are the basis of the superior permanent magnet properties.

The increased density of efficient pinning centers in classical permanent magnets results from high internal stresses (dislocation density) and often from a finely dispersed two-phase

microstructure. Unfortunately it is practically impossible to induce the magnetically desirable crystallographic texture by powder metallurgy; these structures are, however, readily obtained by directional solidification. The fraction of classical permanent magnets produced by PM is therefore decreasing. Oblong AlNiCo magnets have a permanent high-saturation polarization up to values of 1.2 T and an excellent temperature stability [179].

Figure 16. Processing flow chart of modern cut die-pressed permanent magnets [179]

Modern permanent magnets employ ceramic and metallic compounds with crystal anisotropy constants 100-fold higher than those of iron. The most important materials are barium-ferrites, $SmCo_5$ [180], and $Nd_2Fe_{14}B$ [181]. Other basic requirements (e.g., a high saturation polarization and a high Curie temperature) are satisfied mainly by the intermetallic rare earth – transition metal magnets. The basic microstructure of sintered magnets requires defect-free grains of the ferromagnetic phase to avoid local decrease of the anisotropy, the presence of impurities or nonferromagnetic phases at the grain boundaries to prevent magnetic domain walls and flux fields from crossing the boundaries, and well-aligned grains to optimize the total magnetic moment.

For processing cast polycrystalline rare earth – transition metal alloys are crushed and milled to a powder consisting of single crystals (particle size ca. 5 μm). The powders are aligned in a magnetic field, isostatically pressed, sintered, and mechanically cut or ground to customer specifications (Fig. 16). Near net shape magnets are manufactured by die pressing the powders under a strong directional magnetic field before sintering. The parts from both production routes are finally magnetized again either before or after mounting to their final device (e.g., small motors or switches).

Sintering to full density with maintenance of fine average grain size requires careful control of the sintering atmosphere and is often performed in the presence of small amounts of liquid phase (e.g., $Nd_2Fe_{14}B$).

The ferrites are low-cost permanent magnets with typical low saturation polarization values < 0.4 T and coercivities < 300 kA/m. The saturation polarizations of the expensive $SmCo_5$ and $Sm(Co, Cu, Fe, Zr)_{17}$ magnets are 0.9 and 1.15 T, respectively, with simultaneously high coercivities of 1500 – 2400 kA/m. Still higher saturation polarizations of 1.2 – 1.3 T but slightly lower coercivities and a lower Curie temperature (250 –310 °C) are typical for the Fe – Nd – B permanent magnets. The ability of the Sm – Co and Fe – Nd – B magnets to withstand even strong reversed magnetic fields without irreversible losses permits optimization of many devices and reduction of the costs of magnetic systems [179], [182].

Magnetic Composites. Soft magnetic powder composites consist of ferromagnetic particles, which are compacted, and molded. The particles are electrically insulated by an organic or inorganic binder (e.g., a polymer or ceramic). The composites have various advantages (e.g., high resistivity which reduces the losses by eddy currents and isotropic flux conducting properties). Limits are set by the small grain size and the temperature sensitivity of the binder materials. Permanent magnet composites are often

polymer bonded and offer the advantage of easy shaping. A severe drawback is the low magnetic energy density and permanent saturation polarization resulting from a low particle packing density and insufficient magnetic alignment of the particles [179].

9.5. Hardmetals and Cermets

Hardmetals. Hardmetals (cemented carbides, → Hard Materials) consist of a network of hard carbide particles (mainly WC, TiC, and TaC) embedded in a ductile metal matrix (usually Co) [44], [183]. Tungsten carbide or solid solutions of WC – TiC – TaC (for powder production see Section 2.2) are blended with cobalt powder by intensive ball milling for several days under an organic liquid (e.g., acetone, hexane).

A faster method for obtaining homogeneous distribution of the powder components is attrition milling. The addition of paraffin, granulation, or spray drying (Chap. 3) before pressing improves the filling behavior, the homogeneity of the green density, and the green strength of the powders.

Shaping and consolidation at pressures in the range 100 – 200 MPa in uniaxial (e.g., of inserts for metal cutting) or isostatic presses (large parts) or after plastification with an organic binder by extrusion (rods, tubes) yields green densities of ca. 50 % [45]. Dewaxing under humid hydrogen and sintering under dry hydrogen or vacuum at 1350 – 1550 °C are often performed in a single furnace without intermediate cooling. Powder injection molding (Section 5.3) is used for small parts with complex shapes [184]. Sinter – HIP (Section 7.1) yields products with special microstructures such as ultrafine grain sizes [185] or pore-free products from powders with low sinterability.

During sintering of WC and cobalt, a liquid phase forms at or slightly above the eutectic temperature of 1280 °C of the W – C – Co system. At the temperatures used for isothermal sintering (1350 – 1550 °C depending on the composition of the hardmetal) cobalt is completely molten and dissolves up to 25 wt % of the WC. The dissolution – reprecipitation processes described in Chapter 6 lead to densification and grain coarsening.

A major criterion for the quality of hardmetal tools is their tool life which is limited by wear and distortion due to mechanical and chemical interaction with the working pieces. The optimal cutting material has high warm strength, high toughness, and inertness against the working piece. The hardness, pressure strength, and wear resistance decrease with increasing cobalt content whereas the bending strength increases [45]. A reduced WC grain size in the sintered hardmetal improves the hardness and, with fine grain sizes ($<1.5\,\mu m$), the bending strength [185]. Coarse-grained material is used in mining operations. Extremely fine-grained materials are required for drilling in hybrid materials in the electronic industry. Hardmetals containing TiC and TaC are harder than WC – Co and less reactive with steel working pieces at higher cutting velocities. Most of the high-value cutting tool inserts are coated by chemical vapor deposition (CVD) or physical vapor deposition (PVD) with multilayers of TiC, TiN, and Al_2O_3 for improved tool life [185].

Cermets. Today cermets are understood to be hard materials based on multicomponent Ti(C, N) – Ni derivatives sintered in the presence of liquid phase [186]. The expression "Cermets" is an acronym of the words cer(amics) and met(al)s and was originally used to denote metal – ceramic composites. See also → Ceramics, Ceramic – Metal Systems, Chap. 6. Compared to WC – Co hard metals, cermets show enhanced chemical inertness against steel working pieces and reduced topochemical reactions. They allow faster cutting speeds and a reduced cutting wear rate due to higher hardness and cutting edge strength.

Advanced compositions contain molybdenum, tantalum, tungsten, vanadium, and nickel in addition to TiC, TiN, and nickel [187]. During liquid-phase sintering the hard material grains develop a core – mantle structure with a hard core and a tougher mantle [188]. Advanced cermets are beneficially PVD or CVD coated with protective layers.

9.6. Metal – Ceramic Composites

Metal/ceramic composites consist of (1) interpenetrating matrices of a metal and a ceramic

phase, (2) a high volume of ceramic inclusions in a metal matrix, or (3) metal inclusions in a ceramic matrix [189]. They are distinguished from metal – matrix or ceramic – matrix composites in that the main purpose of the ceramic or metal phase is not to improve the mechanical behavior of the base matrix material (as in SiC-reinforced aluminum alloys, hardmetals, or cermets) but to produce materials with specific properties such as thermal expansion or corrosion resistance. Often metal/ceramic and similar composites are manufactured from mixtures of metal and oxide, carbide or boride ceramics, diamond or glass powders by PM processing.

Oxide-based cermets composed primarily of U_3O_8 inclusions sintered in a matrix of aluminum, steel, or tungsten are used in the fuel elements of nuclear reactor cores. They provide better retention of the fission products than pure oxide material and reduce the danger of melting due to their improved thermal conductivity [190].

Excellent corrosion resistance against molten metals and high-temperature strength result in applications for Zr_2O – Mo and Zr_2O – Ti composites as protective tubes for thermocouples to measure melt bath temperatures and for extrusion dies for forming nonferrous metals. Al_2O_3 – Mo composites are used as seals, SiO_2 – (brass/bronze) composites are found as friction materials for heavy-duty brakes or clutches. Electrical contacts are produced on the basis of Ag – CdO and Ag – CrO_2 composites [191].

Boride-based metal – ceramic composites such as ZrB_2 – B are usually used because of their excellent high-temperature corrosion resistance against molten reactive metals.

A major group of metal-bonded composites are metal – diamond materials for grinding, lapping, sawing, cutting, dressing, and truing tools. The metallic matrix is frequently based on cobalt, more rarely on bronze or heavy-metal alloys [192].

Graphite-containing metallic friction materials for brake linings and clutch facings have a predominantly metallic matrix that exploits the high thermal conductivity for rapid energy adsorption. Graphite – copper composites are used for brushes in motors. For brushes with lower rubbing speed and low contact pressure graphite – silver composites are applied.

9.7. Electric Contact Materials

Transmission of electric power and information involves the passage of electric current through numerous devices and components that are joined to one another directly or via wires and leads. The path for power transmission from the generator to the consumer and of information from the sender to the receiver contains ca. 1000 contact points, of which ca. 100 are switching contacts. These switching contacts must switch the current on and off reliably, conduct the current without loss when switched on, and insulate the current paths from one another when switched off. The currents to be switched range from a few milliamps to ca. 100 000 A (e.g., in the case of short circuits at unfavorable points of the power supply network).

Contact components in power engineering generally consist of silver-based composite materials produced by PM. Even precious-metal alloys based on gold and platinum are used for contact components in communication and information technology. Composite materials produced by PM are used in numerous areas in electrical switching devices and switchgear [193–196]. Examples include high-voltage distribution switchgear, industrial and installation switchgear, switches for domestic equipments, switchgear for railways and electrically powered vehicles, and switches for motor vehicles.

Switching contacts have to satisfy many requirements and can be described on the basis of their operational conditions: make operation, current carrying, and break operation.

During *make operation* an arc may be formed after springback of the contacts, this is termed bouncing. As a result the contact surfaces heat up extremely and may weld together when they finally close. This welding tendency of the contact materials should be minimized.

In *current carrying* the contact surfaces only touch one another at a few points, resulting in an electrical contact resistance that causes heating of the contact components. The contact resistance and thus the heating effect should be minimized.

During *break operation* an arc is formed at the contact components, resulting in a high thermal load of the contact material surfaces. The

contact materials should have a low erosion rate and thus a long service life.

9.7.1. Contact Materials for Low-Voltage Switchgear

Most low-voltage switching devices operate in air. Silver is used as the base metal because it does not form nonconducting oxides on the contact surfaces and because it has a high electrical conductivity [195]. Silver is used together with metallic and nonmetallic components in the form of an alloy or composite material to obtain high mechanical and electrical resistance to wear, to suppress the welding tendency, and to assist arc migration and extinction. Powder metallurgy is very important because it is often the only way of producing such materials with their diverse combinations of properties. Worldwide consumption of silver for contact technology in the early 1990s was currently 1600 – 1900 t/a.

Contact materials for air-switching devices can be divided into four groups:

1) Silver and silver alloys
2) Silver – metal composites
3) Silver – metal oxide composites
4) Silver – graphite composites

Figure 17. Transverse (A) and longitudinal (B) cross sections of a AgNi (90/10) composite material

Silver and silver alloys are only used to a small extent in power engineering. They have largely been replaced by particle-reinforced silver composites which have a lower tendency to weld and a longer service life.

Silver – metal composites are mainly produced by powder metallurgy. The most widely used material of this group is silver – nickel; its main advantages are its low contact resistance and simple processibility. It forms nonconducting erosion products, which means that switches made from this material for domestic appliances and process control have a small structural volume combined with a high dielectric strength. Figure 17 shows the fiber-like structure of an AgNi composite material formed by extruding sintered blocks.

Compared to silver – nickel, *silver – metal oxide composites* ($AgSnO_2$, AgCdO, and AgZnO) have a much higher welding resistance at high currents and a longer service life. They are therefore used in switches that have to withstand high current peaks during make operation (e.g., in engines, capacitors, and lamps).

Silver – tin oxide ($AgSnO_2$) is an important development in the field of contact materials [197] because it fulfils technical switching requirements and the need for more environmentally compatible materials with avoidance of toxic substances (cadmium oxide is carcinogenic).

Figure 18. Transverse cross sections of $AgSnO_2$ (88/12) SPW VI (A) and $AgSnO_2$ (88/12) SPW VII (B) after switching on load

Silver – tin oxide is replacing silver – cadmium oxide (AgCdO) which has been successfully used since the early 1950s for applications in the current range from 30 A to several kiloamps. Silver – cadmium oxide exhibits a high resistance to welding, comparatively low heating in continuous operation, and a low tendency to

cut-out burning. These properties are also shared by $AgSnO_2$ materials manufactured by special processes involving special additives. In addition $AgSnO_2$ has a better wear resistance when high currents are switched. Figure 18 shows the structures of two types of $AgSnO_2$ after switching on load [198]. $AgSnO_2$VI (Fig. 18 A) is widely used at present, $AgSnO_2$ VII (Fig. 18 B) is a variant of $AgSnO_2$ VI; the materials differ as regards their additives. Figure 18 A shows $AgSnO_2$ SPW VI after switching loading. The material in the melt zone is permeated by many pores. The "spongy" structure weakens the surface of the material. In contrast, SPW VII (Fig. 18 B) exhibits a stable, "closed" structure in the melt zone, and only a small number of pores are formed.

Silver – graphite composites are also produced by PM. Of all silver-based materials silver – graphite is the most resistant to welding. Its most important field of application is therefore in automatic circuit breakers (e.g., in power switches and power circuit breakers) which must still be able to switch off reliably in the event of malfunction.

The contact materials behave very differently depending on the type of loading they are exposed to. Material tables roughly classify materials according to the type of load [199]. The optimum material combination for a specific application can, however, only be determined by comprehensive switching tests with the contactor in question [200].

The materials are classified in this section according to the criteria used in [199]: welding tendency during make operation and break erosion. The criteria make erosion, contact resistance, etc. are omitted from this classification.

If currents are to be reliably interrupted, for example with automatic circuit breakers, a material must be used that does not weld. Materials are listed below in order of increasing welding tendency.

AgC	3 – 5 % C
$AgSnO_2$	8 – 12 % SnO_2
AgCdO	10 – 15 % CdO
AgZnO	6 – 8 % ZnO
AgWNi	Ni content 10 – 40 %
AgCu	hard silver with 3 % Cu
AgNi	fine-grain silver with 0.15 % Ni
Cu	electrolytic copper
Ag	fine silver

The contact materials exhibit widely differing erosion behaviors in different current ranges. The materials listed below may be regarded as optimal for the indicated switching current ranges:

10 – 1000 A	AgNi
100 – 3000 A	AgCdO
200 – 5000 A	$AgSnO_2$
3000 – 5000 A	AgZnO
> 5000 A	AgW, AgWC

The limits between the current ranges are flexible, especially as the erosion behavior is influenced not only by the current but also by the constructional characteristics of the switching device.

The areas of use of the materials listed above apply to devices that perform frequent switching in air. Since graphite burns under these conditions, AgC has a limited service life. Therefore, AgC is only used in those devices which have a protective function and which must switch rarely occurring fault currents, for example in safety switches.

Production Technology. The PM production of contact materials can be effected in two ways: by extrusion and by individual sintering. Powder metallurgy has the advantage that a wide range of different additives can be combined.

Extrusion comprises the following stages: mixing of the powders, cold isostatic pressing (CIP) of the powders to form extrusion billets, sintering, and extrusion of the billets to form rectangular profiles or wires.

In *individual sintering*, mixing of the powders is also the first step. The individual contacts are then uniaxially pressed, sintered, and recompressed to obtain the required density.

Silver – metal oxide materials can also be produced by *internal oxidation.* Silver alloy billet is first produced by melting and casting. After extruding the billet to profiles or wires, these profiles are cut into contact pieces. These contacts are then annealed in an oxidizing atmosphere to selectively oxidize the alloying elements (e.g., Sn).

9.7.2. Contact Materials for High-Voltage Switchgear

A further group of contact materials are WCu or WAg composites. These materials are used in

high-voltage switches under oil, under SF_6, and in air with currents up to 100 kA. They are usually produced by impregnation methods. High-melting tungsten powder is sintered to form a porous, spongy structure. The pores are filled with molten copper or silver by infiltration techniques. The silver or copper is often alloyed with iron, nickel, or cobalt to improve the wetting of the tungsten structure.

The last group to be discussed comprises contact materials for vacuum switches. The contacts switch throughout their service life under a vacuum $< 10^{-4}$ mbar. One of the advantages of vacuum switches is that they can be used in atmospheres where there is a risk of explosion.

CuCr materials for use in vacuum power switches are most important, particularly in Europe. In materials with a chromium content > 45 wt %, a skeleton is first sintered from chromium powder and then infiltrated with the lower melting component. Chromium contents of 25 – 40 wt % guarantee a satisfactory combination of high welding resistance, high breaking capacity, and low contact heating. These materials are produced by pressing and sintering a mixture of copper and chromium powders. Other switching properties can be improved by using small amounts of additives.

10. Parts with Inherent, Functional Porosity

For a number of products the inherent porosity which results from PM processing route serves a function and is therefore intentionally created and preserved. The most important product groups are filters, bearings, electrodes for biomedical applications, and electrode supports for batteries and storage batteries.

Sintered metal filters are applied for filtering, flame stops, and sound absorption. Most frequently powders from bronze, stainless steel, nickel, titanium, tungsten, tantalum alloys are used. Defined porosities and permeabilities are obtained by the use of spherical initial powders with narrow size distribution. Sintered metal fiber nets also provide filters with effective channel diameters of 0.5 – 200 µm [201].

Sintered self-lubricating bearings are a classical application of powder metallurgy (Section 8.2). The lubricants are stored in the open pores (porosity 15 – 25 %) of the bearings. During rotation of the shaft the lubricant forms a wedge-shaped reservoir and a continuous lubricating film between shaft and bearing. When rotation stops most of the lubricant is withdrawn into the pore space. Due to this reversible process self-lubricating PM bearings require little, if any, maintenance. Materials for bearings are mainly bronze or brass on copper basis but also Fe – Cu – C and Fe – Ni – Cr steels for higher load-bearing applications in the electrical engineering and automotive industries [202].

Sintered electrode plates with porosities up to 80 % are used as electrically conductive frames for the electrode material (e.g., Ni frames for nickel hydroxide in Ni – Cd storage batteries [203]).

Printing inks for the graphics industry are preparations that are transferred to a substrate by means of a printing form. Printing can be either informative, as in texts, or decorative, as with ornaments or pictorial representations.Typographic printing includes the letterpress printing involving raised, hard printing elements and a paste printing ink, and flexographic printing with liquid, quickly drying inks. The offset printing is based on the mutual repulsion between water and fatty printing inks and allows even relatively rough materials to be printed. Other printing processes including gravure printing, screen printing, multicolor printing are described in detail.Pigments in the printing ink industry must fulfill several requirements concerning dispersibility, rheological properties, and transparency. The article gives a list of inorganic and organic pigments, as well as additives that are used in the printing ink technology. A survey of toxicity and economic aspects is also given.

1. Introduction

Printing inks for the graphics industry are preparations that are transferred to a substrate, to which they subsequently adhere, by means of a printing form (definition of the European Printing Ink Assotiation, EuPIA). Printing can be either informative, as in texts, or decorative, as with ornaments or pictorial representations. Materials such as paper, cardboard, sheet metal, glass, plastics, foils, and wood may serve as substrates. In contrast to paints and coatings, print is usually incapable of protecting the substrate material. Typography always presupposes use of some kind of *printing form*. Indeed, printing processes can be classified as a function of the type of form employed (Table 1). Electronic and other special printing processes, such as textile printing, are treated elsewhere and will not be considered here (→ Imaging Technology, → Textile Printing).

Table 1. Characteristics of printing processes and the nature of the corresponding inks

Process	Inking system	Ink	Drying
Typographic			
Letterpress	long, many rollers	paste, remains fresh for long periods	slow; penetration, oxidation
Flexography	very short, 1 or 2 rollers	liquid, rapidly drying	very rapid; evaporation, UV
Lithographic			
Offset	long, many rollers	paste, remains fresh for long periods	slow; penetration, thermosetting, oxidation, UV, electron-beam
Gravure			
Gravure, rotogravure	direct inking	liquid, rapidly drying	evaporates very rapidly; two-component system, UV
Intaglio gravure	short, several rollers	paste, remains fresh for long periods	oxidation, penetration, evaporation
Screen	direct or squeegee	very soft	variable; thick ink layers

The mode of operation of the printing form determines the technology used for inking and thus the drying rate and consistency (viscosity and tack) of the corresponding printing ink (see Section 7.2). These conditions limit the possible formulations, with the result that not every printing process is equally suitable for all printing materials.

In the course of printing, ink must be transported from a reservoir on the printing press to the printing form. The resulting image is transferred in its fresh state either directly or via an intermediate carrier (e.g., a rubber blanket) to the substrate to be printed. The printing ink should then dry very quickly, or at least harden to such a degree that prints will not stick together in a stack or roll, even at high printing speeds. In this process, *resins* are needed to ensure abrasion-resistant binding of the ink solids, possibly to confer gloss to the print, and to produce an ink film with maximum chemical resistance.

2. Typographic Printing

2.1. Letterpress Printing

Forerunners of the letterpress printing process utilized bricks and cut wooden slabs to produce incunabula. Movable type made of clay, wood, or metal was also introduced at an early date in Eastern Asia. Casting instruments for movable type made of a lead alloy, the letterpress, and the associated printing ink were invented by Johannes Gutenberg (1397 – 1468) in Mainz, Germany.

Printing Process. Letterpress printing involves raised, hard printing elements that are evenly and lightly inked with rubber rollers (→ Imaging Technology, Chap. 3.4.2). The paste printing ink is uniformly rolled to a layer thickness of about 1 – 3 µm in long inking devices with the aid of approximately 10 – 20 rubber and metal rollers. The composition of the inks must be adapted so that they dry relatively slowly and do not begin to harden in the inking device.

2.1.1. Cylinder and Flatbed Printing

Printing speeds for sheet-fed flatbed machines reach ca. 3500 sheets/h. Letterpress printing is performed almost exclusively with offset printing inks. If necessary, these inks may be modified slightly with printing aids (see Section 3.1). The dominant position occupied until the 1960s by the letterpress process for high-quality printing on paper has now been assumed by offset printing. The main reasons for this development were the relatively expensive production costs of letterpress forms for text and graphics, time-consuming preparation of the printing press, and problems with ink trapping in multicolor wet-on-wet printing.

For these reasons letterpress machines of both the cylinder and flatbed types are now employed primarily for processes like embossing, stamping, perforation, numbering, and hot embossing, i.e., for work that demands devices with raised patterns and high mechanical pressure.

2.1.2. Newspaper Letterpress Printing

With the plastic plates now used in newsprint rotary letterpress production, it is possible to

achieve rates of ca. 25 000 cylinder revolutions per hour (ca. 8 m/s). The presses themselves are designed to operate at rates as high as about 12 m/s. However, the demand for high print quality on inexpensive newsprint, as in the case of color pictures, encourages the use of rival processes, such as offset and water-based flexographic newspaper rotary printing (Sections 2.2.2 and 3.3).

The print must be still wet when it is drawn over the former of the printing press; otherwise partially dried ink will be deposited on the metal parts. For this reason, dark, rather viscous mineral oils, which penetrate only slowly into paper, serve as "binders". It must also be possible to deink the prints in order to recycle wastepaper. Therefore, like offset newspaper inks (Section 3.3), such inks should be free of substances that undergo oxidative drying or cross-linking. In high-grade black and colored printing inks based on organic pigments, thinner, lighter mineral oils with hard resins function as binders (also bitumen in the case of black ink).

2.1.3. Indirect Letterpress and Dry Offset Printing

When printing uneven, embossed surfaces or molded articles (e.g., cups), an elastic rubber blanket is placed between the printing form and the material to be printed, just as in offset printing. Special printing inks are frequently applied in the printing of plastic beakers. These inks dry when subjected to an energy source (e.g., UV radiation) or partially penetrate into the plastic material (plasticizer as solvent).

The number of possible ink formulations is larger than in wet offset printing because interaction with water need not be taken into consideration.

2.2. Flexographic Printing

Flexography originated in about 1900 as aniline-dye rubber printing, used for simple packaging prints. With the introduction of photopolymer plates, flexography developed in the 1960s into an established graphic printing process using pigmented systems. Flexographic printing inks are liquid, unlike letterpress and offset inks. They dry very quickly.

As in letterpress printing, raised, inked elements of a rubber or plastic printing plate press directly against the material to be printed (→ Imaging Technology, Chap. 3.4.2).

2.2.1. Solvent-Containing Flexographic Printing Inks

A very compact inking system permits the use of low viscosity printing inks that dry quickly by evaporation of solvents (see Table 1). Modern flexo printing presses use laser-engraved ceramic anilox rollers which transfer a well-defined amount of ink to the flexible printing form. The open ink fountains of former times have been replaced by chambered doctor blades. The printing speed is about 400 – 600 m/min, depending on the type of impression. The flexographic process is used for the total range of flexible substrates from paper (shopping bags, gift-wrapping paper, napkins) and board (corrugated, substrates) to nonabsorbing films (e.g., PE, PP, PET, PA) and foils or metallized films.

The composition of flexographic printing inks is very similar to those of packaging gravure inks (see Section 4.1.2). The main difference is the solvent composition and therefore the drying properties, owing to the different distance from doctor blade to printing nip for the two processes. This means that flexographic printing inks contain a higher amount of solvents with lower evaporation rate (retarder). The drying equipment of a common flexo press consists of a hot air dryer.

Because of some advantages in costs (e.g., cheaper print form production), the flexographic process competes with gravure printing even for high-quality reproductions.

2.2.2. Water-Based Flexographic Systems

For environmental reasons the solvents in the inks are increasingly being replaced by water. Especially for absorbent substrates like paper or board, water-based inks are totally replacing solvent-based inks. Modern water-based inks contain only a small amount of solvents (e.g., less than 1 %), and in many applications these ink systems give excellent results without using

any solvent. Much progress has been made in printing water-based inks on nonabsorbent substrates such as PE or PP (shopping bags, heavy duty sacks). Even for these inks the solvent content is below 5 % (alcohol). Wallpaper (with or without plastic coating) can also be printed with specially adapted inks. The printing rate is 200 – 300 m/min, depending on the type of impression.

Drying of water-based inks is performed with the same equipment as for solvent-based inks, but in some cases additional drying with an IR dryer coupled with a cold-air blower can be useful, especially for increasing the printing speed for nonabsorbent films. The drying properties and the final fastness properties are adjusted as required by a special combination of mainly acrylic solutions and acrylic dispersions, solubilized by amines. On drying, the amines are evaporating and a water-resistant film is formed (see also Section 4.1.2).

Typical formulations for water-based flexographic inks are given in Table 2.

Table 2. Typical percentage formulations for water-based flexographic inks

Component	Paper printing	Film printing
Organic pigments	12 – 15	12 – 15
Resin system neutralized with amine (ammonia)	10 – 25	15 – 25
Alcohol (ethanol)		2 – 5
Additives: waxes, antifoamers, dispersing and wetting agents, microbiocides	5 – 7	6 – 10
Water	73 – 53	65 – 45

Water-based flexographic printing has also been introduced in some countries for newspapers, in particular in the United States. The resulting quality is usually superior to that of newspaper letterpress printing with paste inks (Section 2.1.2). The printing speed with waterbased flexography may reach ca. 13 m/s.

The aqueous, hydrophilic flexographic printing inks used today interfere with the deinking flotation process (i.e., the decolorization and reprocessing of old newspapers into fresh newsprint). However, new developments promise solutions to this problem in the near future.

2.2.3. UV-Curing Flexographic Inks

UV-Curing flexographic inks do not lead to air-quality problems because they do not evaporate. Their printability on paper and film is superior to that of water-based inks, and they produce higher gloss and better fastness (e.g., abrasion resistance, → Paints and Coatings). Their composition is similar to that of the UV-curing offset printing inks (Section 3.1.2) but their viscosity is lower.

3. Planographic (Flatbed) Printing — Offset Printing

Planographic printing was introduced as "lithography" (literally writing on stone) by Aloys Senefelder (1771 – 1834) in about 1798. Near the end of the nineteenth century it was developed further into *indirect offset printing*, in which the printing ink is transferred by means of a rubber blanket.

Printing Process. Offset printing is based on the mutual repulsion between water (or an aqueous fountain solution) and fatty printing inks. Whereas printing regions on the plate freely accept the fatty oleophilic inks, nonprinting areas on the same plane are subject to wetting by water (hydrophilic), causing them to repel the ink (see Section 3.4). (In waterless offset printing, a layer of silicone rubber replaces the ink-repelling aqueous wetting agent.) The resulting image is transferred to the printing material via a rubber blanket (for the platemaking process, see → Imaging Technology, Chap. 3.4.1).

A thin, uniform layer of ink is produced with a long inking system consisting of several rubber and metal rollers. For good printability, the inks must be viscous and tacky, and they should not harden in the inking system. For information on the ink – water balance, see Section 3.4. The elastic rubber blanket protects the sensitive printing plate, and it also clings to rough surfaces, permitting even embossed and relatively rough materials to be printed by the offset process. Precoated or raw sheet metal can be printed using special presses. High-quality prints with layer thicknesses of ca. 1 – 3 μm can be achieved.

Production. Pigments are usually supplied as powders that are dispersed in dissolvers and then ground in bead mills and/or three-roll mills with an appropriate oleophilic binder until a very fine dispersion is achieved. Larger particles remain behind and are eliminated.

In another method the finely divided pigments are precipitated from the aqueous phase. They are not dried but transferred directly to the oleophilic phase by a flushing process. The pigments do not agglomerate.

Occupational Health. Laws applicable in Germany stipulate that offset inks be nontoxic or only slightly toxic when used in accordance with regulations. Certain substances must, however, be specified in some countries. Many countries have special regulations for the use of printing inks in food packaging, toys, etc. Waste printing inks are often classified and treated as waste that has to be stored in special, authorized dumps or incinerated under defined conditions.

Substances classified as dangerous have in most cases been replaced by other, harmless materials. Rare exceptions are indicated by appropriate markings on each package.

3.1. Sheet-Fed Offset Printing

Sheet-fed offset printing is used for brochures, calendars, posters, business papers, and packaging (carton and soft packings). Printing speeds of ca. 15 000 sheets/h can now be attained, and speeds of ca. 12000 – 15 000 sheets/h are common.

In the case of absorptive printing materials, drying occurs primarily by penetration of the thin oils into the surface of the paper. This causes the viscosity of the ink to increase rapidly. The resulting firmness is usually sufficient to prevent printed sheets from sticking together in a stack. Depending on the printing material and the ink, the process is complete within a few minutes. Subsequently, cross-linking of oxidatively drying components in the binder occurs under the influence of oxygen. The print achieves a state of final hardness after several hours.

Papers, cartons, etc., often display differing absorptive capacities. Moreover, the oxidative drying process can be appreciably retarded by the presence of unsuitable components in the wetting agent or excessively high water absorption by the inks. Sticking of the drying prints in a stack can usually be prevented by dusting them with finely screened powdered chalk or plant starch.

Typical formulation for sheet-fed offset inks:

Organic pigments	12 – 20 wt %
Binders	
Hard resins	20 – 25 wt %
Soft resins + drying oils	20 – 30 wt %
Mineral oils	20 – 30 wt %
(*bp* 250 – 300 °C)	
Additives	5 – 10 wt %

Sheet-fed offset inks are also used in letterpress printing.

Binders. Interactions with the offset wetting agent must be considered when selecting the types and quantities of raw materials.

Hard resins not only give inks the tack required for good transfer and sharp print, but also confer excellent gloss on the finished print. The most important types of hard resins are rosin modified with phenols and aldehydes and displaying mineral-oil solubilities that lie within a definite range.

The mineral oils should, of course, readily dissolve the resins and keep the ink fresh in the inking system, but on absorptive printing materials, they should also quickly separate from the resin and penetrate into the substrate. In addition to their viscosity and boiling range, their solution properties are also important and are a function of their content of aromatics, naphthenes, and paraffins. Low viscosity accelerates penetration, and good solvent properties retard penetration.

In special sheet fed inks, the mineral oils are replaced by vegetable oils (renewable raw materials) or at least by derivatives of vegetable oils. These modifications are possible without impairing the printability.

Soft resins and drying oils are also good dissolution agents for hard resins. In the presence of driers and atmospheric oxygen these materials undergo oxidative cross-linkage and thereby confer mechanical stability on an ink film. The soft resins are usually fatty alkyds (fatty-acid-modified isophthalic acid polyesters). Drying oils include linseed, soybean, tung, ricinic, and safflower oils.

Additives comprise driers (oxidation catalysts), waxy lubricants for better abrasion resis-

tance (e.g., polyethylene), and anti-setoff powders (e.g., starch) that help prevent sticking of freshly printed sheets.

Pigments. Black paste inks contain special types of carbon black as pigment (see Section 8.1). Reflex blue pigments (e.g., Pigment Blue 56) or other, mostly blue, pigments may be added for toning purposes or to intensify the black effect on the human eye. Gold and silver bronzes and titanium white are somewhat important inorganic pigments (see Section 8.1). For colored organic pigments, see Section 8.2. Inorganic fillers (extenders, Section 8.3) are added as required.

3.1.1. Sheet-Fed Metal Decoration Printing

Metal plates and other nonabsorbing materials obviously are not compatible with the use of high-boiling mineral oils because penetration cannot occur. Oxidatively drying oils and alkyds assume the role of the resin-dissolving agents.

Drying usually takes place in a hot-air oven within several minutes. The baked sheets, perhaps after further lacquering, can be punched or deep-drawn into containers and crown corks. Ink films on cans for the food industry must be resistant to sterilization.

3.1.2. UV-Curing Offset Inks

UV-Curing offset inks are useful in the printing of packaging, labels, and nonabsorbing printing materials. UV printing inks typically contain unsaturated acrylates, polyesters, photoinitiators, and additives. At the end of the press the print is exposed to UV radiation and hardens within a fraction of a second. Printing speeds up to ca. 400 m/min are attained during continuous printing. UV-curing inks are of special interest in continuous form printing when the prints are intended for subsequent processing in a laser printer, where conventional inks cause problems such as evaporation of mineral oils and adhesion of ink on fuser rollers. Because of their high stability and excellent gloss, UV-curing printing lacquers (varnishes) are of interest as gloss coatings for conventional offset and letterpress products.

3.2. Heatset Web Offset Printing

Heatset web offset printing is used for double-sided, four- or five-color printing of medium to large print runs of brochures, magazines, books, etc., with a maximum speed of about 15 m/s. Immediately after the printing process, the paper web passes through a drying oven where it is dried with a high-speed hot air current. The residence time in the oven has to be at least 1 s, which means an oven length for fast-running presses up to 15 m. Mineral oils that volatilize are removed from the exhaust air by afterburning. Heatset inks are expected to release their volatile components as quickly as possible and produce high-gloss printed images. For this reason they contain relatively low-boiling mineral oils (*bp* ca. 200 – 300 °C) and gloss-producing hard resins. The mineral oils should not, however, evaporate on the printing press itself. Their boiling range must therefore be kept within very narrow limits.

Typical formulation for heatset web offset inks:

Organic pigments	15 – 25 wt %
Hard resins	25 – 35 wt %
Soft resins + drying oils	5 – 15 wt %
Mineral oils (*bp* 200 – 300 °C)	25 – 40 wt %
Additives	5 – 10 wt %

Because of the process conditions, compositions for these inks are similar to those of sheet-fed offset inks, although the proportion of oxidatively drying resins and oils is lower, the mineral oils have lower boiling ranges and driers are normally excluded. Process colors predominate in four-color printing, sometimes combined with a spot color.

3.3. Newspaper Offset Printing

As a result of quick, cost-effective platemaking processes and better image reproduction, newspaper offset printing (usually referred to as coldset printing in the UK) has largely replaced newspaper letterpress printing (see Section 2.1.2). Printing inks for this application dry by penetration, and it should be possible to remove them from waste paper by deinking (Section 2.1.2). For this reason they do not contain

binder components that undergo oxidative cross-linking, but rather hard resins dissolved in high-boiling mineral oils (*bp* ca. 260 – 350 °C). Black newspaper offset inks often contain dark, viscous mineral oils and asphalts or bitumen. The pigments are the same as those used in sheet-fed offset printing (see Chap. 8).

Use of an IR dryer to support the drying process allows thicker layers of ink to be printed and, as a result, more brilliant prints even on smooth newsprint paper.

The corresponding printing presses are designed for speeds up to ca. 13 m/s. Actual printing speed approaches 35 000 impressions per hour = ca. 11 m/s.

3.4. Fountain Solutions

The function of a fountain solution in offset printing is to moisten the hydrophilic areas of the printing plate and displace oleophilic inks (see 2.1.3). During the printing process, the fountain solution aids separation of the more viscous ink layer. The fountain solution is emulsified with the ink; emulsification speed, the water-absorbing capacity of the ink, and the particle size of the fountain solution droplets all exert decisive influences on the printing process. A balance must be established: too little fountain solution leads to printing of ink in nonprinting areas, but too much produces buttery, "short" inks in the inking system that fail to transfer properly.

The viscosity and tack of the ink, as well as the static and dynamic surface tension and pH of the fountain solution, represent important physical characteristics with respect to the offset process. Unsuitable ink components may upset the ink – water balance to the detriment of the product and disturb the printing process. Consumption of the fountain solution is in the same range as that of the printing ink and depends on the printed area and the material to be printed.

Typical formulation for wetting-agent concentrates (applied at a concentration of 2 – 5 %):

Buffer system	4 – 8 wt %
Alcohols	5 – 20 wt %
Surfactants	0 – 1 wt %
Hydrophilic polymers	1 – 7 wt %
Complexing agents	0 – 2 wt %
Preservatives	0 – 4 wt %
Anticorrosion additives	0 – 2 wt %
Water, added to make up to	100 wt %

Buffer systems (e.g., citrate buffer) produce a slightly acidic pH, which is effective in the regeneration of the printing plate and offers protection against alkaline substrates (→ Imaging Technology, Chap. 3.4.1). *Alcohols* and *surfactants* reduce the surface tension and improve the wetting power. *Hydrophilic polymers* have been used since the invention of offset printing. Gum arabic is being replaced to some extent by other polysaccharides or cellulose derivatives. The many alcoholic groups in these materials adhere very firmly to the oxide layer of the printing plate, thereby rendering it permanently hydrophilic. *Complexing agents* such as ethylenediamine tetraacetic acid (EDTA) deactivate interfering ions (e.g., Ca^{2+}). *Preservatives* inhibit fungal growth in the fountain solution. *Anticorrosion agents* prevent metallic parts of the printing press from damages.

4. Gravure Printing

Printing processes using printing forms into which the printing areas have been engraved are known as gravure printing (DIN 16 528).

4.1. Rotogravure

Copperplate engraving and etching were forerunners of rotogravure. The first industrial application was the printing of fabrics during the eighteenth century. The beginning of the twentieth century saw the introduction of photomechanical cylinder etching. For modern platemaking, see → Imaging Technology, Chap. 3.4.3.

Printing Process. The printing form in this case is usually a chromium-plated copper cylinder whose printing areas consist of tiny cells. The cylinder is dipped into a thin printing ink which fills the cells. Before the cylinder touches the substrate, excess ink is first wiped off in such a way that ink is transferred only from the cells (see → Imaging Technology, Chap. 3.4.3). Gravure printing is used mainly for printing large numbers of copies (e.g., > 500 000). The preparation of the cylinder is expensive, but very

high printing speeds can be attained because drying proceeds rapidly. The short path from the ink reservoir to the material to be printed via the deeply etched, mechanically and chemically resistant cylinder permits use of rapidly evaporating solvents and a wide range of binders.

Production of Gravure Inks. Powdered pigments and binders, including solvents, are mixed in dissolvers and subsequently dispersed in closed bead mills. Impurities and coarse pigment agglomerates are removed with filter devices such as bag filters.

Pigment preparations (chips) supplied by the pigment industry contain high concentrations of pigments finely dispersed in appropriate binders. Ready-for-use gravure inks are obtained simply by stirring and dissolving these preparations in dilute resin solutions. Such inks are often glossier, more brilliant, and usually more transparent than those made by grinding a powder. However, with this production method the binder cannot be changed at such short notice as in the case of dispersion of dry pigment.

4.1.1. Publication Gravure

This process is employed in the web printing of very large press runs of magazines, catalogs, etc., usually in multicolor applications. Printing speeds attained in magazine printing range up to ca. 15 m/s, with paper widths exceeding 4 m.

Printing Inks. Publication gravure utilizes hard resins dissolved in toluene, in which drying is achieved by solvent evaporation, most of which is recovered from the exhaust air with recovery systems (activated charcoal), thereby ensuring compliance with environmental legislation. Instead of toluene, low-boiling aliphatics and appropriately adapted colophony-based binders may also be used.

Water-based inks like those used in packaging gravure and flexography are not common because of the ease with which toluene can be economically recovered.

Typical formulations for publication gravure inks:

Pigments	ca. 8 – 15 wt %
Resins	ca. 15 – 20 wt %
Toluene (solvent)	ca. 60 – 70 wt %
Additives	ca. 0.5 – 5 wt %

Binders applicable to illustration publication gravure include maleinate resins (rosin modified with maleic acid), phenolic resins (colophony resins modified with phenols and aldehydes), calcium and zinc resinates (rosin "salts"), hydrocarbon resins, ethylcellulose, and bitumen (used only for black inks).

Additives. *Waxes*, often based on polyethylene, enhance surface smoothness (i.e., abrasion resistance) of the print. *Softeners* improve elasticity, and *defoaming agents* prevent foaming in the ink reservoir.

Pigments. Only a few types of pigments are applied in publication gravure because this usually involves four-color process printing with standard colors.

Black:	Pigment Black 7, C.I. 77 266, often shaded toward blue with Pigment Blue 27, Pigment Blue 15 : 3, or Pigment Blue 1, Pigment Blue 56 and 18
Yellow:	Pigment Yellow 12, Pigment Yellow 13
Magenta:	Pigment Red 57 : 1, Pigment Red 81 : 1
Cyan:	Pigment Blue 15 : 3, possibly containing Pigment Blue 27

Occupational Health. According to EC regulations, special labeling is obligatory for toluene. This substance is both highly flammable and damaging to health (→ Toluene, Chap. 8.2). Its classification as a health hazard is continually under review. Printing plants must protect their employees from the effects of toluene by installing equipment that ensures the removal of vapors, encasement of presses, etc., with verification by air monitoring. Pigments and binders are not toxic when used according to directions.

4.1.2. Packaging Gravure

Packaging gravure must be adapted to many different printing materials and the varying demands placed on the printed product. This requires much experience and great flexibility on the part of the printer. Rolls of paper, plastic films, aluminum foils, and laminated stock are all subject to such printing. Depending on the printing press and the object to be printed, printing speeds range between ca. 200 and 400 m/min. In contrast to publication gravure, toluene and aliphatic solvents are not employed. Ethyl acetate and alcohols (e.g., ethanol, 1- and

2-propanol, ethoxypropanol) are the most important solvents. The binders must be adapted to diverse requirements and their compositions therefore vary widely. In food-packaging materials, for instance, only a minimal residual solvent content is permissible.

Cellulose nitrates, polyvinylbutyral, polyurethanes, and other binders in combination with plasticizers are used with alcohols and/or aliphatic esters for many types of paper, lacquered (NC, acrylic) aluminum foils, metallized films, and the whole range of polymer films (PE, PP, polyester, polyamide). Polyethylene and polypropylene films reject printing inks. Print therefore only adheres to them after the film has been subjected to preliminary electrostatic treatment. The most important binder components in this application are cellulose nitrate containing special plasticizers, acrylate resins, polyurethane resins, and polyamide resins with ethanol and ethyl acetate as solvents. Poly(vinylidene chloride) surfaces can be difficult to print. Adherance can be achieved with, for example, mixed polymers of vinyl chloride – vinyl acetate – vinyl alcohol dissolved in ethanol and ethyl acetate. Blocking resistance can be improved with methacrylates or cellulose acetobutyrates. The pigments must be resistant to the plasticizers present.

Binders. Cellulose nitrates are classified according to their degree of nitration into ester-soluble types (nitrogen content ca. 12 %) and alcohol-soluble types, which are also soluble in esters (nitrogen content ca. 11 %). Both types are supplied in varying degrees of polymerization that confer varying levels of solution viscosity. The low-viscosity, alcohol-soluble grades are especially important for printing inks. Their solution viscosity is very high compared to other resins, so concentrations are limited to 12 – 18 %. Hard resins (e.g., maleic resin) are added to increase the solids content, thereby improving the film properties and increasing the gloss of a print.

Since cellulose nitrate is very brittle, the ink film must be made elastic (i.e., softened). Plasticizers are used, and include citrates, and adipates (35 – 50 % based on cellulose nitrate).

Pigments. Corresponding to the wide range of applications of packaging printing, a large variety of pigments is used. In addition to pigments employed in publication gravure, almost all types of organic pigments find application, just as in offset printing. Inorganic pigments include gold bronzes, silver bronzes (aluminum), and nacreous pigments (coated mica), as well as titanium dioxide for white backgrounds on transparent plastic films.

The pigments are responsible for fastness properties (e.g., lightfastness and resistance to migration). An especially good glossy, gold effect can be achieved on aluminum foil with soluble yellow zapon dyes and cellulose nitrate binders.

Additives. Apart from the usual substances applicable to publication gravure, matting agents or antilubricants and other specialties are employed.

Occupational Health. Pigments, binders, and solvents used to print packaging materials are not classified as toxic or even moderately toxic materials. However, almost all the solvents are flammable. If the printing ink contains hazardous substances, it must be labeled in accordance with appropriate regulations. It is the responsibility of the printer to make sure that limiting values (e.g., MAK, TLV values) for volatile substances are not exceeded, and that these defined limits in the outlet air from the dryer are not exceeded. Limiting values with respect to exhaust air can be satisfied if the air is treated before it is discharged. In contrast to publication gravure, this cannot be achieved by adsorption on activated charcoal because the solvent mixtures vary, and may include water-soluble components. The only recourse is to use a thermal afterburner.

Gravure inks must be excluded from wastewater systems.

Gravure with Water-Based Inks. For reasons of environmental protection and occupational safety, gravure inks that are free of, or low in solvent, are becoming increasingly important. Not only paper, but also polyolefin and aluminum foils and other nonabsorbing materials are printed with water-based inks. Inks of this type are also used in the gravure printing of wallpaper.

The advantage of water-based inks is that they create few problems with regard to the outlet air, and they are not flammable. In addition, occupa-

tional safety considerations (MAK, TLV values) do not apply.

As in water-based flexography, the disadvantages are slower drying and the limited choice of binders. Any attempt to accelerate drying by using high temperatures at high printing rates damage a thermoplastic film.

Use of an IR irradiator together with a cold-air blower or longer drying ovens at lower temperatures result in some improvement.

Printing Inks. As in water-based flexography, additives include acidic acrylates which become water soluble when combined with amines (e.g., ammonia, dimethylethanolamine, triethanolamine). A water-resistant ink film remains after evaporation of water and the amine because acidic acrylates are insoluble in water. Prints of this type are not, however, resistant to alkali and detergent. As with water-based flexographic newspaper printing (Section 2.2.2), the extent to which resulting waste paper can be deinked by the flotation process is extremely low, although newer methods have been developed for making water-based inks flotable.

Gravure Transfer Inks. Gravure is the method of choice for printing with transfer inks. Aqueous printing inks containing selected textile disperse dyes are usually printed and dried on special papers. The printed image can then be transferred to the textile materials (e.g., polyester fabric) by pressing at ca. 200 °C. The dyes sublime and are absorbed by the textile fibers, in which they are soluble.

An advantage of this printing process is that production and storage of the paper prints are relatively inexpensive, and high-quality textiles become available at short notice.

Typical formulation:

Disperse dyes	10 – 12 wt %
Acid acrylates + amines	15 wt %
Water	73 – 75 wt %

4.1.3. Special Gravure Inks

The printing of wallpaper, decorative wood, and poly(vinyl chloride) floor coverings imposes special demands. The printed product must be resistant to light and other influences for long periods of time and capable of enduring severe stress, such as high temperatures, during processing. Water-based inks are rapidly gaining prominence here. Special binders and pigments that are resistant to both light and solvents are required. Inorganic pigments retain their importance in this application.

4.2. Intaglio (Steel-Plate Gravure)

Line intaglio or steel-plate gravure is based on the same principle as traditional copperplate engraving. The printing lines are incised into a shiny, polished printing form. However, the cylindrical form is made of Ni – Cr alloy and is chromium-plated. It is prepared for use by stamping it over a matrix.

This process is applicable to the mass production of high-quality items (e.g., banknotes and postage stamps). The corresponding viscous printing inks are transferred from a cutout rubber cylinder to the printing areas of the cylindrical form via a roller inking device. Excess ink is wiped off with a reverse-rotating plastic roller.

Printing occurs directly on the paper under high contact pressure. The wiping cylinder is cleaned after each revolution in an aqueous, alkaline cleaning solution with the help of brushes and doctor blades. It is then dried with air, leaving it clean for the next revolution. High demands for fastness require that selected types of pigments be used. Fillers confer higher viscosity without increasing the tack of the printing ink. Excessive tackiness would impair the wiping process, causing adhesion of the relief-like fresh prints in the stack.

The printing inks dry as a result of oxidation and evaporation of solvent. For this reason, the prints are released for circulation only after a prolonged period of storage. In contrast to gravure, the inks remain raised on the paper even after drying, and they can be felt with the finger.

5. Screen Printing

Screen printing uses stencils made of a fine netlike fabric as the printing form (→ Imaging Technology). The printing inks are viscous, flow easily, and produce layer thicknesses greater than those achieved with other printing processes.

Difficult surfaces (e.g., metals, glass, ceramics, wood, and many different plastics) predominate as printing materials, resulting in many types of prints; some show especially high resistance to light and weather. Examples are posters made of paper or plastic sheet (up to several square meters in size), signs (e.g., reflecting), transparencies, and self-adhesive labels, bottle crates, glass bottles, ampoules, candles, and even pills and eggs. High-quality multicolor artistic posters can also be produced.

Electrical printed circuits, including electrical track conductors, discharge resists, and solder masks, represent a special application of screen printing. Highly efficient equipment has been developed for printing conical or cylindrical objects. In rotary screen-printing machines, the screen is stretched over a cylinder, resulting in what is known as web printing. Printing ink inside the cylinder is forced outward with a squeegee. Printing speeds vary from about 100 prints/h for manual printing to ca. 3000 prints/h (120 m/min) with fully automatic rotary screen devices and fast-drying inks.

Depending on the substrate, the process, and the stability required, a choice may be made from a very wide selection of screen printing inks (two-component inks, inks that are baked or undergo physical, oxidative, or UV drying).

Acrylates are frequently utilized as binder for printing plastics, in some cases together with other resins or polymers. As in gravure printing, vinyl chloride copolymers are suitable for difficult surfaces.

Appropriate organic solvents (e.g., aromatics, aliphatics, ketones, alcohols, and esters) are higher-boiling than those normally employed in gravure printing. Solvent-containing cellulose inks for printing posters may contain up to 75 % aromatic hydrocarbons.

Physically dried inks permit stacking of the prints after passage through a continuous hot-air dryer. Small numbers of slow-drying copies are laid out on a frame.

Screen printing inks that are dilutable with water are becoming increasingly important despite the fact that they are not very weather-resistant.

6. Multicolor Printing

In accordance with color theory, multicolored images are reproduced by superposed printing of the three primary colors cyan (greenish blue), magenta (bluish red), and yellow, as well as black (→ Imaging Technology, Chap. 3.1). Industrialized nations have taken steps toward standardizing all of the stages involved in the use of three-colored and black inks for offset and letterpress printing, including color separation, platemaking, optical properties of the inks, and the actual printing process. The pigments themselves are not specified, however, so technical progress is not impeded. Nevertheless, pigments described in Chapter 8 and recognized as belonging to a "set of pigments for multicolor printing" are normally employed.

The color shades of the inks for four-colour offset printing are standardized in ISO 2846. In the corresponding standards ISO 12647 working procedures for print shops are defined, to reach the standard shades.

Similar standards for publication gravure and flexograhic printing are in preparation.

7. Properties and Testing of Printing Inks

7.1. Fastness Properties

Prints are expected to have fastness properties that are dictated by their use and are obtained by appropriate choice of pigments and binders. National and international standards have been established in the industrialized nations to guarantee the availability of consistent grades of ink with certified characteristics. The fastness of a particular final product also depends on the material to which it will be applied and several other factors; it can therefore vary considerably.

Important properties are:

- Lightfastness (e.g., for posters ISO 2835)
- Fastness to water (ISO 2836) (e.g., for shopping bags)
- Fastness to solvents (ISO 2836) (e.g., fastness to lacquering)
- Fastness to alkali (ISO 2836)
- Fastness to soap (ISO 2836)
- Fastness to detergents (ISO 2836)

- Fastness to cheeses (ISO 2836)
- Fastness to edible fats and oils (ISO 2836)
- Fastness to wax (ISO 2836)
- Fastness to spices (ISO 2836)
- Resistance to sterilization and heat (e.g., for metal cans)
- Resistance to migration (e.g., in printed plastic films)

Print samples are made with inks and tested in accordance with relevant standards. If no testing standard exists, tests are conducted after consultation with the customer.

Lightfastness is assessed in a quick-exposure device (ISO 2835). Half of the sample is covered and the rest is exposed to filtered xenon light until a definite change in color is observed. An eight-level blue wool scale is exposed simultaneously as a reference. Change is characterized according to the following levels:

8	outstanding	4	quite good
7	excellent	3	moderate
6	very good	2	poor
5	good	1	very poor

The length of time over which prints remain resistant to sunlight depends on the strength of the light. For instance, a print with a lightfastness of 6 may require from October to the beginning of May (ca. 225 days) to show the first visible signs of a color change, while the same print exposed from June onward might show the same change after only ca. 45 days.

7.2. Consistency

A printing ink will only produce a satisfactory, standardizable printed result with a particular printing press and print material when its flow properties and tack are appropriate. Flow behavior refers to such properties as viscosity, yield value, and thixotropy. They are highly dependent on the pigment and therefore often differ from ink to ink.

High-speed printing devices require relatively thin inks, whereas slower machines need thicker inks. Both the type of inking unit and the path traversed by the ink from the ink fountain to the substrate to be printed determine the ultimate viscosity range (i.e., whether the ink is thin or viscous, see Chap. 1). Viscosity is measured with a flow cup in the case of thin gravure and flexographic inks, and with a falling bar or rotation viscosimeter for paste inks (offset inks).

The *tack* reflects whether a substance is "short" (like butter) or "long" (flowing but sticky, like honey). It denotes the resistance of an ink film to splitting when distributed on rollers. Ink that is too short cannot be transferred accurately to the substrate to be printed. Ink that is too long (i.e., too tacky) causes "picking" of the substrate when the print rate exceeds a certain value. The tack is not a physically defined measure, but refers instead to a specific tackmeter which measures the drag force. A driven roller is loaded with a certain amount of printing ink, which is distributed with a spreading roller. Measurements of the resulting drag force on a nondriven roller placed above the driven roller are then made. The speed of the driven roller can be varied.

8. Pigments

The production and general properties of pigments are described elsewhere, → Pigments, Inorganic; → Pigments, Organic. Only properties that are important for printing purposes are treated here. Apart from characteristics that depend on the chemical composition of the pigments (e.g., shade, coloring strength, and fastness), the most important considerations in the ink industry are dispersibility, rheological properties, and transparency. These properties are in turn mainly a function of particle shape, particle size, particle-size distribution, and the character of the particle surface, all of which can be heavily influenced by the pigment production method.

8.1. Inorganic Pigments

In general, inorganic pigments are opaque (hiding power), lightfast, and heat-resistant materials that generally display relatively pale colors in impure shades. They also have relatively high densities. The most important products for the ink industry follow.

Pigment White 6 [*1317-80-2*] (titanium dioxide, titanium white), C.I. 77 891, is the pigment with the highest hiding power. It is employed in the anatase and rutile forms, either alone or mixed with colored pigments, in many types of printing inks, especially for flexographic, gravure, and screen printing, as a way of obtaining covering prints on such substrates as transparent plastic films, aluminum foils, and dark paper.

Nacreous pigments are obtained by coating mica with titanium dioxide, leading to mother-of-pearl effects in gravure printing.

Pigment Red 101 and 102, Pigment Brown 6 and 7 (iron oxide and iron silicate pigments), C.I. 77 015, 77 538, and 77 491, are yellow, reddish-brown, and black pigments that are resistant to light, weather, and heat. The transparent reddish-brown pigments are useful, for example, in gravure printing of imitation wood grains. Black and brown iron oxides with magnetic properties are employed for magnetizable printing inks (e.g., for magnetic stripes on credit cards).

Pigment Blue 27 (iron cyan blue, Milori blue, or Prussian blue), C.I. 77 510 is relatively strongly colored. It is used for blue printing inks and as shading components in black letterpress, offset, and publication gravure inks. Apart from poor fastness toward alkalies, its general fastness is good.

Bronzes C.I. 77 000, 77 400: Aluminum powder (silver bronze) and powder made from copper – zinc alloys (gold bronze) are processed to various degrees of fineness and quality for silver and gold effects on packaging and advertising.

Pigment Black 7 [*1333-86-4*] (carbon black), C.I. 77 266: carbon-black pigments are the most important pigments in most black printing inks because of their high coloring strength and excellent fastness.

Important application properties such as color depth, shade, gloss, rheological characteristics, and dispersibility depend upon particle size, surface conditions, and structure. Thus, relatively coarse varieties are used for newspaper inks, and fine types are employed for high-quality black printing inks.

8.2. Organic Pigments

Organic pigments are very important constituents of most printing inks. Organic dyes are losing importance because they display moderate or poor fastness. Approximately 140 000 t of organic pigments were consumed worldwide in 2004 in the production of process printing inks. Pigments are characterized by high coloring strength, pure shades, transparency, and good dispersibility. Lightfastness, resistance to heat, fastness to lacquering, and chemical resistance vary considerably. About 100 organic pigments are suitable for use in printing inks; only the most prominent are mentioned here.

Pigment Yellow 12 [*6358-85-6*] and *13* [*5102-83-0*] (diarylide yellow), C.I. 21 090, 21 100, 21 105, are generally intensely colored, transparent, and resistant to solvents and lacquering. They are utilized in all types of printing inks, especially for the yellow process ink in multicolor printing. Toxic decomposition products may be formed at high temperatures.

Pigment Yellow 12

Pigment Orange 34 [*15793-73-4*] (diarylide orange), C.I. 21 115, is very pure, transparent, and offers good lightfastness and offset printability.

Pigment Red 2 [*6041-94-7*] (naphthol AS red), C.I. 12 310, is a slightly bluish, pure red pigment with good lightfastness.

Pigment Red 57 : 1 [*5281-04-9*] (Rubin 4 B calcium salt), C.I. 15 850, provides moderate to good lightfastness, fastness to lacquering, and fairly good resistance to migration, but it is not stable to many chemicals. In all graphic multicolor printing processes this is the most important pigment for producing the red printing ink "magenta".

Pigment Red 57

Salts of basic dyes are very pure and brilliant. Their lightfastness is usually good, but they are very sensitive to solvents and chemicals. *Pigment Red 81*, rhodamine 6 G laked by precipitation with phosphorus – tungsten – molybdenum acid (PTMA), was previously used as a purple-red scale ink. Other examples are *Pigment Violet 1*, rhodamine B with PTMA, and *Pigment Blue 1*, Victoria blue with PTMA.

Pigment Blue 15 : 3 [*147-14-8*] (phthalocyanine blue), C.I. 74 160, is the most resistant organic pigment. The greenish β-modification is used in all graphic printing processes to provide the cyan for multicolor printing.

Pigment Blue 56 [*64742-56-9*] (reflex blue), C.I. 42 800, is a reddish, intensively colored pigment with average fastness but little resistance to lacquer solvents. It is frequently used to shade black letterpress and offset inks.

Pigment Green 7 [*1328-53-6*] (phthalocyanine green), C.I. 74 260, is a chlorinated phthalocyanine with high fastness, comparable to pigment blue 15. It is pure and transparent.

Polycyclic pigments include the highly resistant but expensive quinacridone, anthraquinone, and dioxazine pigments. They are employed for shading purposes and in specialty inks. The structure of a quinacridone pigment is shown below:

Pigment Violet 19 [*1047-16-1*]

Fluorescent pigments are solid solutions of various dyes in plastic or synthetic resins. They are capable of converting short-wavelength light into long-wavelength light, and they glow brightly when exposed to daylight or, better still, UV light. Resistances are moderate. Fluorescent pigments are used for inks applied to advertising and warning signs as well as packaging.

8.3. Fillers and Extenders

Extenders increase the viscosity of printing inks without simultaneously increasing their tack. They usually offer good transparency, but even small amounts interfere with the gloss of the print.

Aluminum hydrate C.I. 77 002, is used in letterpress and offset inks. Ground with binders, it is also employed as a "transparent white" to tint printing inks. The heavier *clay* (*blanc fixe*), which has somewhat better hiding power, is applied similarly.

Chalk ($CaCO_3$) may be finely ground or precipitated and sometimes hydrophobically coated (e.g., with waxes, fatty acids). It provides a slightly mat effect in paste printing inks.

Silica (SiO_2) is employed in an amorphous, highly disperse form, and is sometimes hydrophobically coated.

Bentonite (montmorillonite) is also coated. Even in small amounts it has a powerful thickening effect in many formulations.

9. Economic Aspects

Production data for printing inks in 2003 (estimation):

World	3 075 000 t/a
North America	830 000 t/a
Europe	1000 000 t/a
Southeast Asia	1 065 000 t/a
Latin America	180 000 t/a

Use in Europe is distributed as follows (2003, CEPE):

Germany	30 %
United Kingdom	17 %
France	12 %
Italy	12 %
Benelux countries	7 %

Market segments in Germany (2004, VdD):

Publication gravure	31 %
Specialty gravure	13 %
Flexography	6 %
Web offset (heatset)	23 %
Web offset (coldset)	12 %
Sheet-fed offset	6 %
Others	7 %

Suppliers (market share):

Worldwide:	7 large producers	(ca. 80 %)
	230 small producers	
Europe:	4 large producers	(90 %)
	80 small producers	
United States:	6 large producers	(80 %)
	110 small producers

1. Introduction

Propanal [*123-38-6*], propionaldehyde, CH_3CH_2CHO, M_r 58.08, is a low-boiling, colorless, flammable liquid with a sharp, suffocating odor. It is found in vegetables such as onions, in cheese and other dairy products, and as an active ingredient in coffee beans, contributing to the aroma of coffee [1].

Propanal is highly reactive, and is employed primarily as a chemical intermediate to prepare C-3 and C-6 compounds. It is generally produced by hydroformylation of ethylene. Annual world production was estimated at 154×10^3 t in 1988 [2].

2. Physical Properties

Propanal is completely miscible with organic solvents such as alcohols, ether, and benzene. Solubility in water decreases at elevated temperature. For example, propanal is miscible with water in all proportions below 15 °C, but becomes less soluble and separates from solution in aqueous mixtures containing ca. 20 – 70 wt % propanal as the temperature increases. Propanal forms azeotropic mixtures with water (98 wt % propanal, *bp* 47.5 °C) and such other compounds as propyl nitrite (82 wt % propanal, *bp* 47.3 °C), 1-chloropropane (*bp* 46.4 °C), and cyclopropyl methyl ether (*bp* 43 °C). Some physical properties of propanal follow [3–7]:

Critical temperature	235.95 °C
Critical pressure	4.660 MPa
mp	−80.0 °C
bp	
101.3 kPa	48.0 °C
40.0 kPa	23.6 °C
1.33 kPa	−38.0 °C

Vapor pressure (20 °C)	34.391 kPa
Refractive index (25 °C)	1.3593
Liquid density (20 °C)	0.797 g/cm^3
Liquid viscosity (20 °C)	0.346 mPa · s
Surface tension (20 °C)	22.95 mN/m
Flash point	
Closed cup	−30.0 °C
Open cup	−7.2 – 9.4 °C
Autoignition temperature	206.85 °C
Lower flammability limit	2.9 vol %
Upper flammability limit	17.0 vol %
Solubility in water (20 °C)	35.6 wt %
Solubility of water in propanal (20 °C)	21.1 wt %

3. Chemical Properties and Uses

Propanal exhibits the characteristic high reactivity of low molecular mass aldehydes such as ease of oxidation and polymerization (trimerization). The reactions are caused by the polarity of the carbonyl group and acidity of the α-hydrogen atoms.

Uses. Propanal has no uses as such; it serves as a source of a propyl group for chemical synthesis. Propanal is primarily converted to 1-propanol, propionic acid, and trimethylolethane (trihydroxymethylethane). Minor applications

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a22_157

include the production of pharmaceuticals (e.g., meprobmat), agricultural chemicals, rubber additives, and corrosion inhibitors.

Reduction. 1-Propanol [*71-23-8*] is the major product of catalytic reduction of propanal (→Propanols). Reduction is carried out most economically by a continuous vapor-phase process over a heterogeneous catalyst of supported reduced nickel, copper, and/or zinc and manganese metals [8–10]. Reaction is normally conducted at 125 – 200 °C and a pressure of about 700 kPa. An advantage of the Cu – Zn catalyst is that it promotes hydrogenolysis of the propanal Tischenko ester (propyl propionate) byproduct to 1-propanol [11]. Liquid-phase reduction on a fixed bed of nickel and copper catalyst is also highly effective in reducing aldehyde to alcohol, but the technique suffers from low efficiency and high cost on a commercial scale.

Oxidation. Propionic acid [*79-09-4*] is produced commercially by liquid-phase noncatalytic air oxidation of propanal [12–14], see also → Propionic Acid and Derivatives, Chap. 4.2. Oxidation proceeds readily at relatively low temperatures (50 – 100 °C), and high aldehyde conversions and acid selectivities (>90 %) are achieved. Continuing efforts are being made to improve the process, particularly oxidation rates, using transition-metal catalysts [15–17]. Major byproducts result from reactions associated with the oxidation process itself, and only a few arise from propanal condensation reactions. Propionic acid is used as a preservative for animal feed and as a chemical intermediate for preparation of sodium and calcium salts added to baked goods, tobacco, and certain vegetables to inhibit the growth of mold and fungus. It is also used to prepare diethyl ketone by passing hot vapors over heterogeneous catalysts such as manganese(II) carbonate [18].

Peroxypropionic acid [*4212-43-5*] ($C_2H_5CO_3H$), useful for peroxidations of olefins, can be obtained by oxidation of propanal with oxygen over a complex-metal catalyst in acetone at 10 – 30 °C and atmospheric pressure in yields >85 % without decomposition of the peroxy acid [19].

Condensation and Addition. Propanal is a key intermediate for the manufacture of trimethylolethane [*77-85-0*] (2-hydroxymethyl-2-methyl-1,3-propanediol) by aldol condensation with excess formaldehyde in the presence of an alkaline catalyst [20–22]. In 1988, 5.4×10^3 t of trimethylolethane was produced and used largely to impart hardness, gloss retention, and durability in alkyd-resin formulations [2].

The two α-hydrogens of propanal can be readily replaced by formaldehyde in a modified Perkin-type reaction catalyzed with a mixture of secondary amine and a carboxylic acid to produce methacrolein [*78-85-3*] [23–26]. Methacrolein yields >90 % are obtained under relatively mild conditions (50 – 100 °C and <1 MPa). Atmospheric oxidation of methacrolein to methacrylic acid and subsequent esterification produces methyl methacrylate [*80-62-6*]. This route to methyl methacrylate appears to be more economical than similar processes starting with propionic acid. If successful, it could open a new major market for propanal [27], [28].

Propanal undergoes self-aldol condensation or cross-aldol condensation with aldehydes or ketones in the presence of aqueous strong alkali in a conventional two-phase liquid process [29]. Self-condensation gives initially the aldol 3-hydroxy-2-methylpentanal [30], which can be dehydrated by heating to 2-methyl-2-pentenal [*623-36-9*]. Typical impurities from the aldol condensation of propanal in alkali at ca. 80 – 100 °C have been identified, and include 2,4,6-triethyl-1,3,5-trioxane, 2,4-dimethyl-2,4-heptadienal, 5-hydroxy-2,4-dimethyl-2-heptenal, 7-hydroxy-2,4,6-trimethyl-2,4-nonadienal, and 3-ethyl-2,4-dimethylvalerolactone [30]. Most of these impurities result from chain lengthening by linear aldolization with 5-hydroxy-2,4-dimethyl-2-heptenal, which is present in significant amounts. The 2-methyl-2-pentenal obtained from dehydration of the propanal aldol intermediate can be readily reduced, oxidized, or made to undergo a variety of addition and condensation reactions. The most useful of these is reduction to 2-methyl-1-pentanol [*105-30-6*] (trade name UCAR Hexanol, Union Carbide Chemicals and Plastics Company, Inc.). Because of its branching, 2-methyl-1-pentanol exhibits lower evaporation rates and lower volatility than 1-pentanol or "primary amyl alcohol" (an industrial blend of 1-pentanol and 2-methylbutanol),

making it useful as a solvent extender and solution viscosity reducer. About 900 t of 2-methyl-1-pentanol was produced in 1990. The corresponding acetate ester was commercially available in 1985 – 1988, but has since been withdrawn from the market.

A continuous process for specific production of the aldol intermediate (97 – 99 % yield) has also been developed [30]. Because of its difunctionality, this β-hydroxyaldehyde is useful for the preparation of pharmaceuticals, plasticizers, and polymers.

Patents describing vapor-phase heterogeneous processes using catalysts such as Pd – rare earth oxides [31], anatase TiO_2 [32], group 11 and/or 12B metals supported on SiO_2 [33], B_2O_3 and/or P_2O_5 supported on TiO_2 or La_2O_3 [34], and La_2O_3, Nd_2O_3, and Sm_2O_3 [35] have been reported. This technique usually gives lower yields (ca. 90 %) and lower aldehyde conversions (<50 %), and it does not challenge the separation simplicity of the two-phase alkali process. Improved conversions (95 %) and yields (88 %) to 2-methylpentanal [*123-15-9*] were reported with a heterogeneous vapor-phase reductive condensation of propanal in the presence of Pd –PrO_3 catalyst on Al_2O_3 [31]. Other vapor-phase reductive condensation catalysts have been described for direct preparation of saturated ketones from cross-aldol condensations of propanal, including Ni, Co, and Zn supported on Al_2O_3 [36] and Mg, Al, Zn, or Te oxides or phosphates and a group 8 metal [37].

The Tischenko reaction can be used for one-step preparation of propyl propionate [*106-36-5*] (a specialty solvent) from propanal, but problems are associated with the aluminum alkoxide catalysts employed in this process. Propyl, butyl, and pentyl propionates are available as specialty solvents from conventional esterification of propionic acid with the corresponding alcohol [38].

A propanal trimer, 2-methyl-1,3-pentanediol monopropionate, used as a solvent modifier for paints, can be obtained from Tischenko rearrangement of the adduct formed between the aldol of propanal and a third molecule of propanal [39]. The nature of the Tischenko reaction of aldols of propanal is discussed in [40].

Propanal is converted to 2,4,6-triethyl-1,3,5-trioxane in the presence of acidic catalysts [41]. The ease of thermal reversion of the cyclic trimer has precluded an utility for materials of this class.

Propanal undergoes reductive catalytic amination with ammonia or primary, secondary, or tertiary amines to the corresponding propyl amine derivatives, which are used as corrosion inhibitors, fuel additives, pharmaceuticals, agricultural chemicals, and rubber additives [42–44]. Substituted pyridines, propionitrile (ethyl cyanide), or acrylonitrile can all be prepared by reaction of ammonia and propanal in the vapor phase depending on the temperature and catalyst employed [45–48].

Propanal can be converted to diethyl ketone, a herbicide intermediate, at high temperature (450 – 500 °C) in the presence of steam and a rare-earth metal-oxide catalyst [49], but propionic acid is the preferred starting material for this ketone [2].

4. Production

Low-pressure rhodium-catalyzed hydroformylation of ethylene with carbon monoxide and hydrogen is the most important process for the production of propanal (→ Oxo Synthesis). Some is still produced in the United States (and all in Europe) by the cobalt-catalyzed hydroformylation process at higher pressure, and a small fraction is obtained in Japan as a byproduct from Wacker oxidation of propene during acetone production [2].

The low-pressure hydroformylation process for production of propanal uses a soluble rhodium catalyst complex with excess triphenylphosphine. Reaction occurs in the liquid phase at 90 – 130 °C and a total pressure of <2.8 MPa with CO pressure <0.38 MPa and H_2 pressure <1.38 MPa [50]. Selectivities are >90 % because ethylene can lead to only one isomer and impurities can be minimized. Major impurities include 2-methyl-2-pentenal, which arises by aldol condensation; trimers from the Tischenko reaction afford 2-methyl-1,3-propanediol monopropionate, which can in turn disproportionate to a mixture of 2-methyl-1,3-propanediol dipropionate and 2-methyl-1,3-propanediol. Byproduct formation during propanal production can be inhibited by exclusion of oxygen, organic acids, and metal contaminants such as iron, which act

as Lewis-acid catalysts for its condensation to higher products.

5. Quality Specifications

Propanal purity is determined by gas chromatography using a capillary column. Care should be taken to ensure that the injection port is clean and low in temperature (<200 °C) to avoid condensation of propanal in the port.

Common impurities include butanal, 2-methylpropanal, aldol products, and various trimers. Typical specifications for high-purity-grade propanal follow [51], [52]:

Propanal	99.5 wt %, min. (dry basis)
Acidity	0.1 wt %, max. (calculated as propionic acid)
Distillation (103 kPa)	initial *bp* 46.0 °C, min.; after 97 mL, 50.0 °C max.
Water content	1.0 – 2.5 wt %
Color	20 Pt – Co, max. (ASTM)
Iron content	20 ppm by weight, max.

Water is generally added to stabilize the pure concentrated aldehyde against condensation to cyclic trimers or acyclic oligomers, catalyzed by Lewis acids such as iron, and to decrease peroxide formation on standing [53].

Table 1. Production of propanal derivatives in 1988 [2] ∗

Compound	Production, 10^3 t	
	United States	Western Europe
1-Propanol	88.5	11
Propionic acid	47.2	
Trimethylolethane	2.7	
Others	1.4	2

6. Economic Aspects

Propanal is produced in the United States by Eastman Kodak, Hoechst Celanese, and Union Carbide Chemicals and Plastics Company, Inc. About 138 000 t was produced in 1988 in the United States [54]. In Europe, production is lower. The average annual growth rate for propanal during 1988 – 1993 is estimated to be ca. 0.8 % [2]. In 1988 an excess capacity for propanal manufacture of ca. 25 %.

Traditionally, propanal production has depended on the demand for 1-propanol and propionic acid, which account for more than 90 % of the aldehyde consumed (Table 1).

7. Storage and Transportation

Propanal should be stored in stainless steel, baked phenolic-lined steel, or aluminum containers to avoid contamination with metal salts present in the construction materials, which at >3 ppm can cause propanal condensation. Stainless steel is most commonly employed. Condensation can also be caused by light and oxygen, and it is particularly troublesome in high-purity samples. Storage at low temperatures is not protective.

Propanal is highly reactive and forms explosive peroxides on exposure to air. Storage under a nitrogen atmosphere is recommended; addition of water also reduces peroxide formation and provides stabilization against metal-catalyzed condensations [53]. Contact with other oxidizing materials should be avoided. Caution is advisable with emptied containers containing residual vapors, which may explode on ignition.

Propanal is a volatile and flammable liquid that can present a flammability hazard under normal storage conditions. It has a relatively high vapor pressure and low flash point. Important flammability data are given in Chapter 3.

8. Toxicology and Occupational Health

Acute exposure through inhalation of propanal vapor causes extreme irritation of the eyes and may irritate the respiratory tract. High concentrations may also cause drowsiness, headache, nausea, and difficulty in breathing. Contact of the liquid with the eyes or skin causes burns. Ingestion is irritating to the gastrointestinal tract, causing burning in the mouth and throat, nausea, abdominal discomfort, and diarrhoea [55].

The oral acute toxicity data reported for rats is LD_{50} 1410 mg/kg; specific toxic effects have not been described [56]. The oral LDLo for mice is 800 mg/kg [55]. The dermal LD_{50} for rabbits is 5040 mg/kg, showing slight absorption; no toxic

effects were noted [56]. Severe skin irritation resulted with guinea pigs.

Propanal is a severe irritant to rabbit eyes [56]. The inhalation LCLo for rats is 8000 ppm (4 h) and in humans the LC_{50} is 21.8 g/m^3 [55]. Propanal is an anesthetic when inhaled in relatively high amounts by rats [57]. Preliminary edema was the cause of death in mice and rabbits after inhalation of high levels of propanal [57]. Exposure of rats to vapor (0, 90, or 1300 ppm, 6 h/d, for 20 consecutive exposures) showed the lowest-observed-effect level (LOEL) at 1300 ppm (liver damage) and the no-observed-effect level (NOEL) at 90 ppm [53].

TLV and OSHA PEL values have not been established for propanal.

1. 1,2-Propanediol and Higher Propylene Glycols

1,2-Propanediol, [*57-55-6*], propylene glycol, $HOCH_2CH(CH_3)OH$, is very similar to ethylene glycol in its physical and chemical properties (→Ethylene Glycol). The first reported description of propylene glycol was by Wurtz in 1859 [1].

Industrial-scale synthesis of propylene glycol from propylene oxide (→Propylene Oxide) and water began in the 1930s. Current production uses this same process, which leads simultaneously to di- and tripropylene glycols. The worldwide capacity for propylene glycol is estimated to be 9×10^5 t (1990) [2]. Production may be lower because some propylene glycol production units are designed to permit switching to ethylene glycol output depending upon relative demand for the glycols.

Propylene glycol is used in many diverse applications such as unsaturated polyesters (→Polyester Resins, Unsaturated) for thermoset composites, food chemistry, food processing equipment, cosmetics, and pharmaceuticals. A growing application is in the field of deicers and automotive antifreeze components (→Antifreezes).

1.1. Physical Properties

Propylene glycol is a clear, colorless, strongly hygroscopic liquid. The higher propylene glycols (di- and tripropylene glycol) have similar properties. Dipropylene glycol [*110-98-5*] exists as three isomers differing in the positions of the methyl substituents, and tripropylene glycol [*24800-44-0*] is typically a mixture of several isomers. All three glycols are moderately viscous liquids that do not readily crystallize, but solidify to vitreous masses upon cooling. Fundamental physical properties of these diols are listed in Table 1 [3–9].

Figure 1. Solidification temperatures for aqueous propylene glycols
a) Tripropylene glycol; b) Dipropylene glycol; c) Propylene glycol

Propylene glycol is readily miscible with water and other polar solvents (e.g., alcohols and acetone). Propylene glycols are good solvents for many polar organic substances, such as phenols, alcohols, dyes, natural products, and some resins. Propylene glycol is insoluble to sparingly soluble in such nonpolar solvents as petroleum ethers, benzene, aromatic hydrocarbons, and carbon tetrachloride.

Figure 3. Density of aqueous propylene glycols at 20 °C
a) Tripropylene glycol; b) Dipropylene glycol; c) Propylene glycol

Propylene glycol greatly reduces the freezing point of water and is therefore being developed as an alternative to ethylene glycol in automotive antifreeze systems [10], [11] and aircraft deicers [12], [13]. The solidification temperatures of propylene glycol and its higher homologues at varying water ratios are plotted in Figure 1. The viscosities and densities of aqueous propylene glycol solutions are plotted in Figures 2 and 3 [4].

Vapor pressure versus temperature curves for the three propylene glycol homologues are plotted in Figure 4. Propylene glycol forms azeotropes with the solvents listed in Table 2 [14].

1.2. Chemical Properties

The chemical properties of propylene glycol are determined predominantly by its hydroxyl groups, and its reactions are typical of alcohols (→ Alcohols, Aliphatic). Propylene glycol condenses with carboxylic acids at elevated temperature to yield esters and water. It also reacts readily with isocyanates and acid chlorides to yield carbamates and esters, respectively.

Propylene glycol undergoes polycondensation reactions with diacids to yield polyesters. Predominant among such applications is the re-

Table 2. Azeotropes with propylene glycol [14]

Cosolvent	Cosolvent *bp*, °C	Azeotrope *bp*, °C	Propylene glycol, wt %
o-Nitrophenol	217	186	>62

action with maleic anhydride and other diacid components to yield unsaturated polyesters [15], [16] (see above).

Propylene glycol reacts with propylene oxide to form dipropylene glycol, tripropylene glycol, and polyether polyols. The resulting polypropylene glycol ethers are important industrial building blocks for polyurethane foams and elastomers (→Polyurethanes) [17], [18].

Because of its 1,2-diol structure, propylene glycol also undergoes a variety of interesting cyclization reactions. Cyclic acetals and ketals are formed with aldehydes and ketones, respectively [19].

At elevated temperature in the presence of an acidic catalyst, propylene glycol can undergo dehydration to yield cyclic ethers. Very low levels of these dehydration products are common in aqueous byproduct streams of polycondensation reactions involving propylene glycol [20].

Propylene glycol is unusual in that the commercial product is a racemic mixture of two chiral isomers. Only small quantities of chiral material are available from specialty chemical distributors.

Figure 4. Vapor pressure versus temperature for propylene glycols
a) Tripropylene glycol; b) Dipropylene glycol; c) Propylene glycol

1.3. Production

The only industrial process for manufacturing propylene glycol is *direct hydrolysis of propylene oxide* with water. Dipropylene glycol and tripropylene glycol are formed by sequential addition of propylene oxide to propylene glycol. Consequently, all three products are produced simultaneously and separated by distillation.

Propylene oxide and water are combined in the initial stage of the process at a molar ratio of 1 : 15 at an initial temperature of 125 °C and a pressure of approximately 2 MPa (Fig. 5). Due to the exothermic reaction [21], the reactor effluent temperature will typically rise to 190 °C. At the above ratio of water to oxide, the resulting propylene glycol – dipropylene glycol – tripropylene glycol mixture is approximately in the ratio of 100 : 10 : 1. Higher propylene glycol ratios are attained by increasing the water-to-oxide ratio; however, such an increase also increases recycle rates, lowers throughput, and raises energy costs.

The water – glycol mixture exits the reactor zone (a) at about 200 °C and is stripped of water in dehydration columns (b). Three successive vacuum distillations (c – e) separate high-purity propylene glycol, dipropylene glycol, and tripropylene glycol. The residue represents a mixture of higher glycols, which have some limited commercial use. Waste from this process is extraordinarily low. Because of the very low toxicity of propylene glycol, dipropylene glycol, and tripropylene glycol, these materials represent a minimal hazard to the environment. All are readily biodegradable.

Alternative routes to propylene glycol have been investigated. Acetoxidation of propene to yield glycol acetates followed by hydrolysis to the glycol has been reviewed [22]. This technique involves lower production costs than the propylene oxide route, but fixed capital investment costs are much higher. Direct hydroxylation of propene to propylene glycol using oxygen in the presence of osmium catalysts has been reported [23–25]. However, because of the ready availability of propylene oxide, the simplicity of the current process, and the extremely low level of waste generated by the propylene oxide route, no alternative process has yet been commercialized.

1.4. Quality Specifications

At least two commercial grades of monopropylene glycol exist – a high-purity industrial grade, and a higher-purity grade called "super pure" or "U.S.P." grade. Typical assays for the two grades of propylene glycol are the same; however, the U.S.P. grade is used in applications such as pharmaceuticals, cosmetics, and food additives, and entails higher quality standards (see Table 3) [4].

Table 3. Typical properties of commercial propylene glycol [4], [26]

Property	Industrial grade	U.S.P. grade
Purity, %	99.5	99.5
d_{20}^{20}	1.0377	1.035 – 1.037
Distillation initial *bp*, °C	185	185
dry point, °C	190	189
Acidity, wt % as acetic acid	0.005	0.002
Chlorides, ppm as Cl (max.)	10.0	1.0
Iron, ppm (max.)	1.0	0.5
Heavy metals, ppm [a]		5.0
Arsenic, ppm as As (max.)		3.0
Sulfate, wt % (max.)		0.006
Water, wt % (max.)		0.2

[a] All metal residues are calculated as if they were lead.

1.5. Transportation and Storage

Propylene glycol, dipropylene glycol, and tripropylene glycol are stable materials that require no special handling procedures. They are noncorrosive and can be transported or stored in stainless steel, aluminum, and lined steel containers. Carbon steel is also acceptable, although slight iron contamination may occur upon extended periods of storage. U.S.P.-grade propylene glycol is typically stored in stainless steel. The glycols are hygroscopic, and should be protected from unnecessary exposure to the atmosphere.

1.6. Economic Aspects

Worldwide capacity for propylene glycol production is summarized in Table 4. These capacity figures are flexible, because the same facilities can also be used to produce ethylene glycol depending upon market pressures. Actual production in the United States in 1989 is estimated

Figure 5. Schematic of propylene glycol production
a) Reactor; b) Evaporator (typically 2 – 4 columns; c) Propylene glycol distillation column; d) Dipropylene glycol distillation column; e) Tripropylene glycol distillation column

to have been 3.65×10^5 t, approximately 95 % of capacity [27].

Table 4. Worldwide capacity for propylene glycol production in 1990 [2]

Region	Number of manufacturers	Capacity, 10^3 t/a
North America	5	384
Western Europe	6	361
East Asia	7	118
Total	18	863

1.7. Uses

Propylene Glycol. The single largest use of propylene glycol is in the manufacture of unsaturated polyester resins. It is reacted with saturated and unsaturated carboxylic diacids such as isophthalic acid and maleic anhydride. The resulting resins are dissolved in styrene or another polymerizable monomer, then combined with filler, chopped glass, a peroxide polymerization initiator, and other additives, and cured to yield a hard, cross-linked, thermoset composite [15], [16], [21]. The end-use applications for such products include automotive plastics, fiberglass boats, and construction. Roughly 45 % of the propylene glycol produced goes to this one broad application [5].

Propylene glycol has many diverse applications in the food and pharmaceutical industries because of the "Generally Regarded As Safe" (GRAS) status conferred on it by the FDA in the United States. Propylene glycol is used as a humectant, solvent, and preservative in food and pet food products. In the manufacture of food products, propylene glycol is used as a lubricant for machinery, as a solvent in food processing, in food wraps, and as an antifreeze agent in machinery cooling water. Propylene glycol is also used as an emollient, softening agent, and humectant in skin- care products and cosmetics, and as a carrier for livestock medicinal products [4], [7].

Propylene glycol is utilized in aircraft deicing and anti-icing fluids because of its proven performance, low toxicity, ready biodegradability, and environmental acceptance [13]. It offers freeze protection similar to that of ethylene glycol, the principle component of automotive antifreeze solutions. Automotive antifreeze compositions incorporating propylene glycol have been investigated [10], [11], [28].

Propylene glycol is useful as a lubricant in combination with di- and tripropylene glycols. It is commonly employed as a humectant for tobacco. Propylene glycol is also introduced into many latex paints as a freeze – thaw protector, and to provide evaporation control in hot and dry environments. Propylene glycol is reacted with fatty acids or long- chain carboxylic acids to produce ester lubricants, emulsifiers, and plasticizers [29–31].

Propylene glycol is a precursor of many polyether polyols used in the urethane foam, elastomer, adhesives, and sealants industry, whereby the compound is reacted with propylene oxide and/or ethylene oxide in order to generate a low molecular mass polyether [17], [18].

Dipropylene and Tripropylene Glycols. Both glycols are used in hydraulic fluids and brake fluids because of their high stability and low corrosion properties. They are also used in inks and some paints because of their good solvency for pigments and binders, very low evaporation rates, and low toxicity. Stamp pad inks are a prime example [32]. Dipropylene glycol has some application in refining operations because it facilitates the separation of aromatic and aliphatic hydrocarbons. Di- and tripropylene glycols are precursors of low molecular mass esters and polyesters, which have utility as plasticizers and lubricants. Both glycols are also used to make polyester polyols for urethane applications.

1.8. Derivatives

The major end-use derivatives of propylene glycol, dipropylene glycol, and tripropylene glycol are unsaturated polyester resins as well as low molecular mass ester and polyester plasticizers. Propylene glycol-initiated polyethers are also modest-volume commodity products.

The class of materials known as glycol ethers (propylene glycol alkyl ethers) is commonly referred to as propylene glycol derivatives, but most of these are actually propylene oxide-derived products because of the ease with which they can be prepared from the oxide. Nevertheless, some glycol ether products actually are derived from the glycol – most notably propylene glycol mono-*tert*-butyl ether, which is produced by reacting propylene glycol with isobutene [33]. These derivatives find application predominantly in coatings and cleaners.

2. 1,3- Propanediol

1,3-Propanediol [*504-63-2*], trimethylene glycol, $HOCH_2CH_2CH_2OH$, is produced on a much smaller scale than its isomer, propylene glycol. In spite of some interesting areas of application, total production remains relatively small. The difficulties of manufacturing the product result in a poorly competitive price structure relative to other diols.

2.1. Properties

Key physical properties of 1,3-propanediol are as follows [3], [34]:

M_r	76.10
mp	−27 °C
bp (101.3 kPa)	214 °C
bp (0.7 kPa)	94 °C
Vapor pressure (20 °C)	0.008 kPa
Vapor pressure (100 °C)	0.98 kPa
d_{20}^{20}	1.0554
d_{4}^{20}	1.0529
Refractive index n_D^{20}	1.4389
Kinematic viscosity	46 m^2/s
Flash point	80 °C

1,3-Propanediol is a clear, colorless, odorless liquid that is miscible with water, alcohols, ethers, and formamide. It is sparingly soluble in benzene and chloroform.

The chemical properties of 1,3-propanediol are typical of alcohols. Like 1,2-propanediol, 1,3-propanediol condenses with carboxylic acids at elevated temperature to yield esters. It also reacts with isocyanates and acid chlorides to yield urethanes and esters, respectively. Unlike 1,2-propanediol, 1,3-propanediol has two primary hydroxyl groups with equivalent reactivity.

1,3-Propanediol readily forms ethers. 3,3′-Dihydroxydipropyl ether forms upon continued reflux of the diol. 1,3-Propanediol reacts with aldehydes and ketones, often in the presence of acidic catalysts, to form 1,3-dioxanes [35], [36]:

Over aluminum oxide at temperatures above 250 °C, 1,3-propanediol decomposes to allyl alcohol, propanol, and other products.

1,3-Propanediol reacts with diacids to form polyesters. The polyester with terephthalic acid is reported to have a crystalline melting point of 220 °C [37]. Polyurethanes can also be synthesized from 1,3-propanediol.

2.2. Production

1,3-Propanediol is prepared by a two-step process involving the hydrolysis of acrolein to 3-hydroxypropanal followed by hydrogenation [3], [38]:

$$CH_2{=}CH{-}CH{=}O + H_2O \longrightarrow HO{-}CH_2CH_2CH{=}O$$

$$\xrightarrow[\text{Cat.}]{H_2} HO{-}CH_2CH_2CH_2{-}OH$$

Hydrolysis is carried out under weakly acidic conditions in water containing initially ca. 20 % acrolein. Higher concentrations of acrolein tend to lead to greater amounts of undesired byproducts as a result of reaction between acrolein and hydroxypropanal.

3-Hydroxypropanal can be hydrogenated in the aqueous phase directly; however, the preferred technique is to extract the aldehyde into an organic solvent – particularly 2-methylpropanol – and then hydrogenate the aldehyde to yield the diol. Hydrogenation is conducted with Raney nickel under pressure in the aqueous phase and with nickel-supported catalysts at 2 – 4 MPa and 110 – 150 °C in the organic phase [39]. The diol is subsequently separated from solvent and water by distillation.

The yield of desired product by this route is relatively low – approximately 45 %. Alternative techniques for synthesizing the diol have appeared in the patent literature. Hydroformylation of ethylene oxide followed by hydrogenation yields 1,3-propanediol in good yield (92 %), but a high catalyst concentration and a very large excess of solvent render the process uneconomical [40]. More recently, hydroformylation of ethylene oxide directly to 1,3-propanediol with a rhodium – phosphine catalyst system has been disclosed [41]. The reaction of ethylene with formaldehyde and carboxylic acids has also not been commericialized because of low selectivity [42].

Handling of 1,3-propanediol is similar to that of propylene glycol. The material is noncorrosive and can be transported in stainless steel, aluminum, or lined steel vessels.

Quality analysis is readily accomplished by gas chromatography. A good technical grade generally displays a purity between 98.5 and 99.5 %.

The environmental impact of this product is expected to be low because of its low toxicity and ready biodegradability. The handling of acrolein in the production process must be carefully controlled.

2.3. Uses

As a diol, 1,3-propanediol is subject to many of the same polymeric applications as other low molecular mass diols (e.g., ethylene glycol, propylene glycol, and 1,4-butanediol). However, its relatively high price limits its use to applications requiring very specific performance characteristics. It is a raw-material source for 1,3-dioxanes. 1,3-Propanediol-bis(4-aminobenzoate) [*57609-64-0*] can be used as a chain extender in polyurethane elastomers. This bisbenzoate, which can also be synthesized from 1,3-dichloro-propane, finds other applications as a cross-linking agent in epoxy formulations and as a rubber additive.

3. Toxicology

1,2-Propanediol. The toxicological properties of 1,2-propanediol have been reviewed [3], [4], [43]. The substance has such a low order of acute toxicity that it is considered practically nontoxic. Since 1942 it has been classified as an acceptable ingredient in pharmaceutical applications, and the United States FDA permits its use in food products and cosmetics. Official requirements for 1,2-propanediol used as an adjuvant in pharmaceuticals can be found in international and national pharmacopeias.

Acute oral LD_{50} values for rats range from 21.0 to 33.7 g/kg. For mice the values range from 23.9 to 31.8 g/kg. Tests with other animals (guinea pig, rabbit, mouse, and dog) yield LD_{50}

values within the same range [43]. These values correspond to ingestion of 1.5 – 2.0 L by a typical adult human.

Administration of single, almost lethal doses to laboratory animals have caused balance disorders resulting from central nervous system depression. Significant impairment of motion was observed in rats after oral administration of 19.5 g/kg. A similar level of impairment was observed with an ethanol dosage of only 1.5 g/kg.

Propylene glycol is not injurious to the eye of rabbits, and it is not known to have caused any eye injuries in humans. Slight transitory stinging and tear formation may result from direct contact with the eye.

Propylene glycol does not produce any significant irritation effects in skin contact with rabbits or humans, although skin irritation has been reported in some individuals when high concentrations were held in contact with skin under closed conditions [44], [45].

Subchronic and chronic studies also indicate that propylene glycol has a low order of toxicity. A two-year study on rats demonstrated that incorporation of 5 % propylene glycol into the diet did not increase or accelerate mortality. No tissue damage was noted at 7.5 % of the diet for 20 weeks, but at 20 % of the diet the rats exhibited nonspecific minor changes in liver and kidney cell structure [46].

Studies also indicate that propylene glycol does not present a health risk after inhalation. Monkeys and rats exposed to propylene-glycol-saturated atmospheres for 12 – 18 months showed no adverse effects [47].

In vivo and in vitro mutagenicity tests show no mutagenic behavior [48]. Reproductive studies with mice, rats, hamsters, and rabbits show no effects upon fetal development, and no teratogenic effects. In a reproductive study with rats, a level of 7.5 % propylene glycol in food showed no effects over six generations [49].

In the body, propylene glycol is metabolized mainly to carbon dioxide via pyruvic acid, but it also enters into carbohydrate metabolism and promotes glycogen formation. At higher dose levels, some propylene glycol is excreted in the urine.

No permissible exposure levels have been established, because none appear to be necessary.

Dipropylene Glycol and Tripropylene Glycol. These two glycols have not been studied as extensively as propylene glycol, but both are considered to possess a low order of toxicity. The oral LD_{50} values in rats for dipropylene glycol and tripropylene glycol are 15 g/kg and 12 g/kg, respectively. In a subchronic study involving 5 wt % dipropylene glycol in drinking water, rats were not affected. However, at 10 % some rats died, and there was evidence of liver and kidney involvement.

Both di- and tripropylene glycol demonstrate negligible eye and skin irritation. Continuous or repetitive application of the two glycols provides no indication that toxic quantities are absorbed through the skin. Because of low vapor pressures and low systemic toxicity, inhalation hazards appear negligible.

1,3-Propanediol. 1,3-Propanediol is mildly toxic. The oral LD_{50} for rats is 14 – 15 g/kg, whereas intraperitoneal LD_{50} values for rats and rabbits are 6 – 7 g/kg and 3 g/kg, respectively [50]. Prolonged administration to chickens inhibits growth [51]. Unlike its isomer, propylene glycol, 1,3-propanediol is not permitted for use in food or livestock feed products.

1. Introduction

The propanols C_3H_7OH, M_r 60.10, comprise two isomers, 1-propanol [*71-23-8*] and 2-propanol [*67-63-0*], also called isopropyl alcohol, of which the latter is industrially the more important. Both are clear, colorless, flammable liquids with a slight odor resembling that of ethanol. They occur in nature in crude fusel oils and as fermentation and decomposition products of various vegetables.

The propanols are used mainly as solvents for coatings; in antifreeze compositions and household and personal products; and as chemical intermediates for the production of esters, amines, and other organic derivatives. 2-Propanol is produced by hydration of propene, while 1-propanol is manufactured by the hydrogenation of propanal, in turn derived from hydroformylation of ethylene. Annual U.S. production of 1-propanol and 2-propanol is estimated in 1988 to have been 98×10^3 t and 630×10^3 t, respectively [1].

2. Physical Properties

The propanols are completely miscible with water and readily soluble in a variety of common organic solvents (e.g., ethers, esters, acids, ketones, and other alcohols). Physical properties of anhydrous 1- and 2-propanol as well as a 91 vol % azeotropic mixture of 2-propanol with water are provided in Table 1. Physical properties of the propanols reflect the position of the hydroxyl group. Associative properties in solution cause the propanols to form azeotropes with a variety of compounds, including aromatics, esters, amines, and ketones. Examples of binary azeotropes of 1- and 2-propanol are given in Table 2.

Freezing points of 1-propanol – water and 2-propanol – water mixtures are plotted in Figure 1. These plots show that the advantages of a substantially lower freezing point for pure 1-propanol relative to 2-propanol are lost in aqueous solutions of the two alcohols.

Figure 1. Freezing points of 1- and 2-propanol – water mixtures [2], [17]

3. Chemical Properties

The differences in reactivity between 1-propanol and 2-propanol reflect the influence of the nature of the hydrocarbon radicals in primary and secondary alcohols, respectively. Characteristic reactions of the hydroxyl group include dehydrogenation, oxidation, esterification, amination, and dehydration. The chemical properties of greatest commercial importance are discussed below.

Propyl ether	85.8	32.2	78.2	52

Dehydrogenation (Oxidation). 2-Propanol can be readily dehydrogenated to acetone (→ Acetone, Chap. 4.2.), although the process is being replaced by the cumene – phenol process and by direct oxidation of propene (as developed by Wacker – Hoechst).

$$(CH_3)_2CHOH \xrightarrow{\text{Catalyst}} (CH_3)_2CO + H_2 \quad \Delta H = 67\ \text{kJ/mol}$$

Pure dehydrogenation of 2-propanol can be accomplished in the liquid or gas phase with a zinc – copper catalyst at 300 – 500 °C and 300 kPa to give ca. 90 % selectivity to acetone and 98 % 2-propanol conversion. Selectivity can be increased to 96.8 % by employing a Cu – Zn – Cr catalyst [18]. Dehydrogenation is endothermic and requires high temperatures.

Dehydrogenation can also be conducted oxidatively in the presence of silver or copper catalysts at 400 – 600 °C [19].

Patents describe a 2-propanol dehydrogenation process for the production of a mixture of acetone, methyl isobutyl ketone, and higher ketones [20], [21]. For example, vapor-phase dehydrogenation of an azeotropic mixture of 2-propanol and water over a copper-based catalyst at 220 °C yields a product mixture containing acetone (52.4 %), 2-propanol (11.4 %), methyl isobutyl ketone (21.6 %), diisobutyl ketone (6.5 %), and 4-methyl-2-pentanol (2.2 %) [20].

Partial oxidation of 1-propanol can be achieved with air in the presence of catalysts to form propanal and propionic acid [*79-09-4*]

[22]. Strong oxidizing agents such as nitric acid react exothermically with both alcohols, giving a complex mixture of products.

Esterification. The propanols can be converted into propyl esters by reaction with organic and inorganic acids using the conventional method for esterification in the presence of mineral-acid catalysts. The commercially important *n*-propyl acetate [*109-60-4*] and isopropyl acetate [*108-21-4*] are produced by direct esterification of the corresponding alcohols with acetic acid in the presence of sulfuric acid, *p*-toluenesulfonic acid, methanesulfonic acid [23], [24], or a strong cationic resin [25] as catalyst. A higher-pressure (170 – 310 kPa) continuous process at 110 – 160 °C with continuous removal of product ester and water has been described, which should offer higher production rates [26]. 1-Propanol can also undergo ester interchange with methyl or ethyl acetate in the presence of a strong cationic exchange resin to give *n*-propyl acetate [27].

Reaction of 2-propanol with CS_2 in alkaline solution produces xanthate esters. The method simply involves refluxing the alcohol with alkali-metal hydroxide in trichlorofluoromethane solvent while adding CS_2 [28], [29]. Sodium isopropyl xanthate, $(CH_3)_2CHOCSSNa$ [*140-93-2*], is a herbicide used for weed control.

Reaction of 2-propanol with phosphorus halides proceeds readily to form phosphite esters. Generally, reaction is conducted in a solvent containing an acid scavenger, but a new solventless spray method could have merit [30].

Titanium(IV) isopropoxide [*546-68-9*] and titanium(IV) propoxide [*3087-37-4*] are made by reaction of the corresponding alcohol with $TiCl_4$ in refluxing heptane with removal of HCl coproduct [31]. These esters are especially useful as polymerization and transesterification catalysts.

The propanols also form esters upon reaction with active metals. For example, aluminum isopropoxide [*555-31-7*] and aluminum propoxide can be prepared by contacting aluminum with alcohol vapor [32], [33]. These materials find use as catalysts, in the preparation of aluminum soaps, as dispersants in paint formulations, and as starting materials for ceramics.

Reaction with Ammonia and Amines. Both 1- and 2-propanol can be reductively aminated by reaction with ammonia or lower amines to give propylated amine derivatives. The reactions are normally conducted at 1.0 – 10.0 MPa and 190 – 250 °C using catalysts consisting of nickel, aluminum, cobalt, molybdenum, and/or chromium. Alcohol conversions are usually ca. 90 % [34]. For example, $H_2 - NH_3$ – 2-propanol (12: 8: 1 mole ratio) was passed over a nickel-based catalyst at 110 °C in the vapor phase at a liquid hourly space velocity (LHSV) of $1\,h^{-1}$ to give a mixture of 93.5 % isopropyl amine [*75-31-0*] and 6.3 % diisopropyl amine [*108-18-9*] with a 2-propanol conversion of 93 % [35].

Etherification and Dehydration. 1-Propanol and 2-propanol can be reacted with one, two, or three moles of ethylene oxide, propylene oxide, or both to give a family of glycol ethers having broad utility as solvents. Reaction is generally catalyzed by alkali hydroxide.

Diisopropyl ether [*108-20-3*] can be prepared by liquid-phase dehydration of 2-propanol at 130 – 190 °C and 1.96 – 7.85 MPa over acidic catalysts containing aluminum [36], [37]. Dehydration of 1-propanol to di-*n*-propylether [*111-43-3*] can be accomplished with a cation-exchangeable layered-clay catalyst containing titanium or zirconium at 180 °C [38].

The dehydration of 1- or 2-propanol to give propene has no practical value. Nevertheless, dehydration is most facile with 2-propanol in the presence of mineral acid catalysts at room temperature or higher, conditions that should otherwise be avoided in most instances.

Others. The propanols give hemiacetal adducts readily on addition to aldehydes. The products can in turn be converted to acetals with a second mole of alcohol under dehydration conditions in the presence of an acidic catalyst [39]. Acetals find use as intermediates in the preparation of pharmaceuticals.

2-Propanol can be condensed with such aromatic compounds as toluene and phenol to produce isopropoxylated derivatives.

4. Production

1-Propanol and 2-propanol are produced by very different processes starting from ethylene and propene, respectively.

4.1. Production of 1-Propanol

Propanal, obtained by hydroformylation of ethylene (→ Propanal), is the primary commercial source of 1-propanol. In a second step the propanal is hydrogenated to 1-propanol.

$$CH_2 = CH_2 + CO + H_2 \xrightleftharpoons[\text{pressure}]{\text{Catalyst, heat,}} CH_3CH_2CHO$$

$$CH_3CH_2CHO + H_2 \xrightleftharpoons[\text{pressure}]{\text{Catalyst, heat,}} CH_3CH_2CH_2OH$$

Hydroformylation of Ethylene. Union Carbide Chemicals and Plastics Company, Inc. [40], and Hoechst Celanese practice the two-step oxo process based on rhodium-substituted phosphine-catalyzed low-pressure hydroformylation technology (→Oxo Synthesis, Chap. 3.1.), while Eastman Kodak Company uses a higher-pressure cobalt-based process for production of the intermediate propanal [1]. Typical oxo conditions employed in the low-pressure rhodium-catalyzed oxo process are 90 – 130 °C, <2.8 MPa total pressure, with CO at <380 kPa, H_2 at <1.4 MPa, and <500 ppm rhodium [41]. Conditions of the cobalt oxo process are 110 – 180 °C, 20 – 30 MPa (200 – 300 atm), 1: 1 to 1: 2 H_2: CO ratios, and 0.1 – 1.0 wt % cobalt based on ethylene [42]. The crude propanal is removed by vapor stripping with excess synthesis gas, and the rhodium – triphenylphosphine catalyst is recycled [40]. Traces of CO are removed in a stripping column from the crude, condensed propanal before hydrogenation to prevent poisoning of the hydrogenation catalyst in the second step. The higher selectivity and milder conditions of the rhodium-catalyzed process provide crude 1-propanol for hydrogenation containing fewer impurities, such as higher aldol-condensation products and aldehyde trimers (Tischenko esters).

Hydrogenation of propanal is conventionally carried out as a heterogeneous process in either the vapor or liquid phase over a variety of metal catalysts. Heterogeneous vapor-phase processes are effective at ca. 110 – 150 °C, and 0.14 – 1.0 MPa at a 20: 1 mole ratio of hydrogen to propanal [43–45]. Reductions are accomplished in excess hydrogen, and the heat of reaction is removed by circulating the vapor through external heat exchangers or by cooling the reactor internally [46].

Hydrogen efficiencies are >90 %, with aldehyde conversions as high as 99.9 % and alcohol yields >99 %. The commonly used commercial hydrogenation catalysts include combinations of copper, zinc, nickel, and chromium compounds. Major impurities at vapor-phase process temperatures are dipropyl ether, ethane, and propyl propionate. In addition to reduced zinc oxide and copper oxide catalysts, selectivity enhancers such as alkali and transition metals can be added to significantly reduce the formation of esters (by Tischenko reaction of the starting aldehyde) and ethers [44]. Addition of 1 – 10 % water to the reactor feed also suppresses ether formation [47].

The propyl propionate byproduct formed in the catalytic hydrogenation can be separated and hydrogenolyzed in the presence of reduced CuO – ZnO catalyst at 75 – 300 °C and 9.8 kPa – 9.8 MPa to give 1-propanol as the major product [48].

Liquid-phase heterogeneous processes are conducted at higher pressures. For example, hydrogenation at 95 – 120 °C and 3.5 MPa of hydrogen gives 1-propanol with >99.9 % purity. Nickel- and copper-based catalysts containing molybdenum, manganese, and sodium promoters are preferred [49]. The catalysts are usually supported on alumina.

Other processes have been described for the preparation of 1-propanol; for example, in two steps by isomerization and hydrogenation of propylene oxide [50]; from synthesis gas [51], [52]; from methanol [*67-56-1*] and synthesis gas [53]; and by the Guerbet reaction [54].

4.2. Production of 2-Propanol

There are two major commercial processes for the production of 2-propanol: indirect and direct hydration of propene. Smaller quantities are produced by hydrogenation of acetone.

Indirect hydration involves two steps. In the first, a mixture of mono- and diisopropyl sulfate esters is formed from reaction of propene with sulfuric acid. The reaction is exothermic, yielding about 50 kJ/mol.

$$3\,CH_3CH{=}CH_2 + 2\,H_2SO_4 \rightleftharpoons (CH_3)_2CHOSO_3H + [(CH_3)_2CHO]_2SO_2$$

The sulfate esters are then hydrolyzed to product 2-propanol in a second step.

$$(CH_3)_2CHOSO_3H + [(CH_3)_2CHO]_2SO_2 \xrightarrow{H_2O} 3\,(CH_3)_2CHOH + 2\,H_2SO_4$$

A major byproduct in the indirect process is diisopropyl ether, which is formed from reaction of the sulfate esters with product 2-propanol.

$$(CH_3)_2CHOSO_3H + [(CH_3)_2CHO]_2SO_2 \xrightarrow{(CH_3)_2CHOH} 2\,[(CH_3)_2CH]_2O + 2\,H_2SO_4$$

Other impurities include hydrocarbons, char, polymeric residues (oils), propanal, acetone, and odorous sulfur-containing compounds. Isopropyl sulfate esters are particularly unstable, decomposing at temperatures as low as 50 – 100 °C [55]. Mono- and disulfate esters can be thermally desulfonated to give SO_2, SO_3, and a mixture of propene and acetone.

$$(CH_3)_2CHOSO_3H \xrightarrow{Heat} CH_3CH{=}CH_2 + SO_3 + H_2O$$

$$(CH_3)_2CHOSO_3H \xrightarrow{Heat} CH_3COCH_3 + SO_2 + H_2O$$

The indirect hydration process can be conducted with either strong or weak acid. A schematic for an indirect *weak-acid hydration* is shown in Figure 2.

Propene-containing feed gas (propene content $\leq 60\,\%$) is reacted with ca. 60 % H_2SO_4 in a series of absorption columns (a) at 75 – 85 °C and 0.59 – 1.0 MPa. Production rates and efficiencies are linked to a balance of initial sulfuric acid concentration, temperature, total pressure, and propene partial pressure. High absorber temperatures favor ether formation. The propene is sparged into the lower portion of the absorbers while the H_2SO_4 is fed to the top to establish a countercurrent flow pattern. The "sulfates" product stream is taken from the bottom of the absorbers and fed to vacuum strippers (b) where it is hydrolyzed with steam and the resulting 2-propanol is flashed as overhead product. Product-free acid bottoms (recycle acid) from the strippers are concentrated to about 60 % and recycled to the absorbers. The required reconcentration of acid in this process is less costly than in the strong-acid process, where reconcentration to >90 % is required. Vaporized stripper product is neutralized by scrubbing with caustic (c), and uncondensed vapors (vent gas) are combined with the blow-off gas from the scrubbers and recycled to the reaction.

Figure 2. 2-Propanol production by indirect, weak-acid process
a) Absorbers; b) Strippers; c) Caustic scrubber; d) Scrubber; e) Liquifier

Crude 2-propanol is fed to a multicolumn refining system where a constant-boiling mixture (CBM) of 2-propanol is obtained. Byproduct diisopropyl ether is recovered as a lights stream from the first column in the refining train and recycled to the reaction absorbers, where it is hydrolyzed back to product, thus preventing ether accumulation in the process:

$$[(CH_3)_2CH]_2O + H_2O \xrightleftharpoons{H_2SO_4} 2\,(CH_3)_2CHOH$$

Heavy-end concentrated oils are also collected and discarded.

The main problem encountered in purification of 2-propanol is its separation from water. Enrichment of the CBM to >99 % or absolute 2-propanol is accomplished by use of an azeotroping agent, which forms a ternary constant-boiling mixture. Diisopropyl ether and cyclohexane are common entraining agents for 2-propanol enrichment [56]. Undesirable intense odors inevitably arise from sulfur-containing compounds, and this can cause difficulties in such commercial uses as cosmetic products, spray products, and medicinal formulations. Odor is generally removed by contacting the 2-propanol with ion-exchange resins, activated carbon, activated alumina, or metals (e.g., copper, nickel) [57–59].

The weak-acid indirect hydration process suffers from high corrosion rates and disposal problems with water, acid, caustic, and off-gas wastes. A major advantage is the ability to use low-purity propene feed. Advances in waste minimization include replacement of the lead-lined absorbers with corrosion-resistant ceramics and synthetics.

Indirect hydration is still the primary process conducted in the United States by Exxon, Shell Oil, and Union Carbide Chemicals and Plastics [60], while Lyondell Petrochemical produces a smaller amount by hydrogenation of acetone [60]. There are indications that a few companies in Europe and Japan may also be employing this older technology [19].

In the *strong-acid process* reaction is conducted with a high sulfuric acid concentration (> 90 wt %), while the pressure and temperature are low compared to the weak-acid process (1.0 – 1.2 MPa and 20 – 30 °C, respectively). Hydrolysis is accomplished in a separate second stage. Both processes offer 2-propanol selectivities of >90 wt %.

It is reported that for 1 t of 2-propanol produced, 0.8 t propene, 0.35 t H_2SO_4, 3.5 t steam, and 40 – 50 kW · h of electricity are required in an optimized process [61]. It is believed that the strong acid process is not employed as a major commercial source of 2-propanol in the world today because of the requirement for high-purity propene feedstock and waste-disposal problems.

Direct Hydration. The direct hydration of propene has been in commercial use since 1951.

$$CH_3CH{=}CH_2 + H_2O \underset{}{\overset{\text{Catalyst}}{\rightleftharpoons}} (CH_3)_2CHOH \quad \Delta H = -50\ \text{kJ/mol}$$

High pressures and low temperatures over an acidic fixed-bed catalyst characterize this process, causing the exothermic equilibrium reaction to be displaced to the right. Three versions of the direct hydration process are practiced commercially today.

1) Low-temperature (130 – 160 °C), high-pressure (8.0 – 10.0 MPa) vapor – liquid phase hydration over a sulfonated polystyrene ion-exchange resin catalyst was pioneered by Deutsche Texaco [62–69]. The feed, consisting of propene gas and liquid water, is fed in a supercritical state to the top of a fixed-bed reactor and allowed to trickle downward. Feed containing about 92 % propene can be used, resulting in propene conversions of about 75 % per pass. About 5 % diisopropyl ether and about 1.5 % oxygenates (alcohols) of propene oligomers (hexenes) are formed as byproducts. This technique requires high-pressure equipment, and could suffer from problems of short catalyst life. This technology and plants based on it are licensed outside Europe [70].
2) High-temperature, high-pressure (270 – 300 °C, 20 MPa) vapor – liquid hydration of propene over a reduced tungsten oxide catalyst was developed by Tokuyama Soda [71–73]. This process utilizes a molar ratio of water to propene of about 2.5: 1. Water is present in both the gas and liquid phases, which increases conversion (because equilibrium is shifted farther to the right due to the solubility of 2-propanol in water). This technology requires high-pressure equipment, but features high propene conversions of 60 – 70 % per pass and 2-propanol selectivities of 98 – 99 % based on converted propene. The catalyst must be durable (stable in the presence of water). The process has low gas-recycle requirements, so propene of only 95 % purity can be used.
3) ICI developed technology for vapor-phase hydration of propene involving medium to high pressures. This process uses a WO_3 – SiO_2 catalyst at 250 °C and 25 MPa [19], [74], and it gives yields of about 95 %. In Germany, VEBA developed a similar hydra-

tion process based on a phosphoric acid catalyst supported on SiO_2 and operated at 180–260 °C and 2.5–6.5 MPa [75–77]. Typically, these processes require high propene recycle (less than 10 % conversion per pass) and utility costs are probably high. High-purity propene (~99 %) is required. The phosphoric acid process is commercial in Germany, the Netherlands,the United Kingdom,and Japan.

Hydrogenation of Acetone. Hydrogenation can be conducted in the liquid phase over a fixed catalyst bed of a Raney-nickel catalyst to give 99.9 % selectivity and 99.9 % conversion of the acetone [78], [79]. Hydrogenation over copper oxide–chromium oxide at 120 °C and 196 kPa gives lower selectivities and conversions (98 % and 94 %, respectively) [80]. It is not essential that the acetone be pure. This process is particularly advantageous where excess acetone is available as a byproduct from another process (e.g., the cumene–phenol process).

Other Processes. Patents have been issued describing the manufacture of 2-propanol from cellulosic materials (e.g., cotton, corn, and wood) [81], [82].

5. Uses

Uses of the two propanols are dictated by their solvent properties, their high water miscibility, and by their potential for introducing the propyl group into chemical intermediates.

1-Propanol. In 1988 over 75 % of the 1-propanol in the United States was employed in solvent applications, either directly or in the form of acetate ester or glycol ether derivatives [1]:

Solvent uses	24 900 t
1-Propyl acetate	19 500 t
n-Propylamines	11 300 t
Glycol ethers	5 400 t
Others	2 300 t
Total	63 400 t

As a solvent, 1-propanol is used principally in printing inks, paint, cosmetics, pesticides, and insecticides [83].

The EC used about 100 000 t of 1-propanol in 1988 [84]. In Germany, BASF converts most of its propanal into 1-propanol for printing inks, cosmetics, solvents, and intermediates for propylamines used in pharmaceuticals and pesticides [1]. In Japan, 1000–2000 t of 1-propanol was consumed in 1988 for printing inks and paints, all of which was imported [1].

1-Propanol is used commercially to produce glycol ethers. These are characterized by dual functionality, which imparts high solvency, chemical stability, and water compatibility. Glycol ethers such as ethylene glycol monopropyl ether (from 1-propanol and 1 mol of ethylene oxide), diethylene glycol monopropyl ether (from 1-propanol and 2 mol of ethylene oxide), propylene glycol monopropyl ether (from 1-propanol and 1 mol of propylene oxide) and dipropylene glycol monopropyl ether (from 1-propanol and 2 mol of propylene oxide) are marketed by Union Carbide Chemicals and Plastics [85] and Eastman Chemical Products [86].

n-Propyl propionate [*106-36-5*] is a new solvent available from Union Carbide Chemicals and Plastics and developed for use in automotive refinishing, appliance coatings, and high-solids coating systems [85]. *n*-Propyl propionate is touted as a replacement for the isomeric *n*-butyl acetate in coatings, where improved odor characteristics are desirable.

2-Propanol. 2-Propanol is used primarily as a solvent in inks and surfactants [70]. Other applications include its role as an antiseptic alcohol, as a reaction solvent for cellulose carboxymethyl ether [*9000-11-7*] (CMC), in the production of cosmetic base materials and pesticide carriers, as a source of material for organic synthesis, for washing of a flux used in soldering electrical circuits, and for removal of water from gasoline tanks in cars [70]. Table 3 shows approximate consumption data for 2-propanol in both 1986 and 1990 in the United States.

The coatings use of 2-propanol has reached a plateau due to a shift toward waterborne and high-solids coatings. Its use as an electronics solvent is growing, but the market is small [89]. 2-Propanol is a particularly versatile solvent for producing high-performance (e.g., gelation-resistant and polyamide-containing) printing inks [90]. In the pharmaceutical industry, 2-

propanol enjoys favor as a processing solvent during manufacture of drugs.

Use of 2-propanol for the production of acetone has decreased dramatically. There remains only one acetone plant in the United States (compared to four in 1985), and the market is still oversupplied [91]. However, since the cumene route to phenol provides equal amounts of phenol and acetone (→Acetone), a strong demand for acetone relative to phenol can increase the need for acetone production from 2-propanol [88].

2-Propanol is widely used as a chemical intermediate, for example in reductive amination to produce monoisopropyl amine (for herbicide and pesticide production), and as a source of isopropyl acetate. Some diisopropyl amine is utilized as an intermediate in the synthesis of diisopropylammonium nitrate, a corrosion inhibitor [91].

Nippon Petrochemical has begun marketing pure 2-propanol (99.99 %) for use in high-purity large-scale integration (LSI) and silicon wafers for the electronics industry [92]. Another attractive new application is as an octane enhancer, carburetor anti-icing additive, and methanol cosolvent in motor gasoline blends [93].

2-Propanol is useful in extraction processes; thus, aqueous solutions are utilized in liquid–liquid extractions of fatty acids from vegetable oil at temperatures as low as −2 °C [94].

Table 3. 2-Propanol consumption in the United States (10^3 t) [87], [88]

	Year	
	1986	1990
Coating solvents	8.2	9.1
Processing solvents	6.4	6.8
Household/personal	6.4	5.4
Pharmaceuticals	6.4	5.4
Acetone	4.5	3.6
Miscellaneous solvent applications and chemical intermediates	4.5	3.2
Exports	9.1	11.8
Total	45.5	45.0

6. Specifications

ASTM standard specifications for propanol are given in Table 4.

Product purity is generally determined by capillary gas chromatography. Typical purities specified by manufactures for 1- and 2-propanol are 99.7 – 99.9 wt % and 99.8 wt %, respectively. Because of its use in packaging, 1-propanol may sometimes be required to pass a specific odor test conducted for consumers by an odor panel. Occasionally, alkalinity and propanal content are included in the requirements for 1-propanol.

7. Economic Aspects

Manufacture of the propanols in major industrial countries is summarized in Table 5.

Since 2-propanol is no longer the primary feedstock for acetone it will see little, if any, growth in the United States unless new applications are found. In 1989 production units there were currently operating at about 60 – 80 % of capacity [96]. United States output of 2-propanol was 649×10^3 t in 1989 [97], and forecasted to grow to only 726×10^3 t by the year 2000 [98]. Demand fell by 4.4 %/a in 1977 – 1986 to 578×10^3 t in 1986 due to the decrease in use for acetone production [99]. The capacity for 2-propanol in Western Europe is roughly comparable to that in the United States. It was estimated based on U.S. import/export data that Western Europe in 1991 operated at or near full 2-propanol capacity.

2-Propanol production in Japan has been rising by about 5 %/a. Demand in Japan reached 130×10^3 t in 1989 [100], with steady growth (3 – 4 %) in paints and solvents and rapid growth (15 – 20 %) in detergent applications [101]. In 1990 there was a shortage in Japan [100].

Nippon Petrochemicals (50 %), Tokuyama Soda (25 %), and Mitsui Toatsu Chemicals (25 %) are the three major producers of 2-propanol in Japan [70]. Tokuyama Soda employs its own direct hydration technology based on a tungsten catalyst, while Nippon Petrochemicals uses technology developed by VEBA [70].

8. Storage and Transportation

The propanols are flammable liquids, and should be considered dangerous fire risks when exposed to heat or flame. Explosive limits for propanols in air are 2 – 12 %. Some important data for the safe handling of propanols are given in Table 6.

Table 4. ASTM Specifications for propanols

	1-Propanol	2-Propanol	Specification method
ASTM standard	D 3622-90	D 770-90	
d_{20}^{20}	0.804 – 0.807	0.785 – 0.7870	
d_{25}^{25}	0.801 – 0.804	0.782 – 0.784	D 268 or D 4052
Color, Pt-Co (ASTM)	10	10	D 1209
Distillation range, 101.3 kPa	distill within a 2 °C range that includes 97.2 °C	distill within a 1.5 °C range that includes 82.3 °C	D 1078
Nonvolatile matter, mg/100 mL	5	5	D 1353
Water, max, wt %	0.1	0.2	D 1364 or D 1476
Acidity, acetic acid, max, wt %	0.003	0.002	D 1613

Table 5. 1-propanol and 2-propanol manufacture in major producing countries (10^3 t) [95]

Country	Production of 1-propanol in 1988	Capacities of 2-propanol		Production of 2-propanol in 1994
		1991	1996	
United States	98	791	740	658
France		115		
Germany	5 [a]	215	220	175
Japan	0	209	160	130
Netherlands		250		
United Kingdom		190		
Western Europe			750	570

[a] Production for merchant market.

Table 6. Safety data and transport regulations for propanols [102]

	1-Propanol	2-Propanol
Flash point (open cup), °C	15.0	11.7
Flammability limits in air, vol %	2.0 – 12.0	2.0 – 12.0
Autoignition temperature, °C	371.11	398.89
Vapor pressure at 20 °C, kPa	1.9854	4.4053
Percent in saturated air, 25 °C	2.7	5.8
Density in saturated air, (air = 1), 25 °C	1.028	1.06
Heat of combustion, MJ/kg	−33.60	−33.35
U.N. No.	1274	1219
RID/ADR	Class 3, number 3 b	Class 3, number 3 b
IMDG Code	Class 3.2	Class 3.2
CFR 49	172.101 flammable liquid	172.101 flammable liquid

Care should be taken during heating (e.g., distillation) of old samples of 2-propanol. Several violent explosions have been reported during attempts to concentrate old samples to small volume, suggesting that this compound should be classed as peroxidizable (via autoxidation of the tertiary hydrogen) [103].

Baked phenolic-lined steel or stainless steel tanks are recommended for storage and shipping of the propanols in order to maintain high quality. Mild steel tanks are also adequate providing a filtering system is installed to remove rust [104]. Storage and transport under dry nitrogen is also recommended to protect against moisture pickup and to minimize flammability hazards. Aluminum is not recommended. The flash points of the propanols are low enough so that the compounds can be stored underground under a nitrogen atmosphere. Pipes and pumps can be constructed from the same metals as the storage facility. Centrifugal pumps with explosion-proof electric motors are suitable [104].

Table 7. Toxicity of propanols in animals [107]

	1-Propanol	2-Propanol
LD_{50} rat (oral), mg/kg	1 870 [a]	5 045 [b]
LD_{50} rabbit (intravenous), mg/kg	483 [a]	1 184 [a]
LCLo rat (inhalation), ppm/4 h	4 000 [a]	12 000 [a], ppm/8 h
Eye injury, rabbit	20 mg/24 h, moderate 4 mg, open severe	10 mg, moderate
LD_{50} rabbit (cutaneous), mg/kg	5 040 [a]	12 800 [a]

[a] No description of toxic effects.
[b] Behavioral (altered sleep time).

Table 8. Odor detection limits for propanols [106]

	Absolute odor threshold [a], ppm	50 % Odor recognition [b], ppm	100 % Odor recognition [b], ppm
1-Propanol	<0.03	0.08	0.13
2-Propanol (anhyd.)	3.20	7.50	28.2

[a] This is the concentration at which 50 % of an odor panel observed an odor.

[b] The concentrations at which 50 % and 100 % of the panel defined the odor as due to propanol, respectively.

9. Toxicology and Occupational Health

The propanols are considered to have generally low toxicity in humans [102]. Ingestion of excessive dosages of 2-propanol by alcoholics and suicidals has been reported to cause poisoning due to depression of the CNS and respiratory irritation. Repeated or prolonged contact with propanols may cause drying of the skin. The propanols display an exposure warning because they can cause mild to severe irritation to the eyes, nose, and throat. However, adverse effects are rare in light of widespread use by the general public and considerable industrial exposure [102], [105].

Animal studies reveal irritation to the eyes, low acute oral toxicity, and low irritation to the skin, as shown by the data in Table 7.

The mean exposure limits for 1- and 2-propanol in air at the workplace by ACGIH (TLV) and OSHA (PEL) are 200 ppm and 400 ppm, respectively. The MAK value for 2-propanol is 400 ppm. Odor threshold data are provided in Table 8.

The propanols are registered in the Toxic Substance Control Act (TSCA) and the European Inventory of Existing Commercial Substances (EINECS).

1. Introduction

Propellants are explosive agents that generate large amounts of hot gases by an exothermic reaction without the need for atmospheric oxygen. This process is generally initiated by supplying thermal energy. Burning occurs vertically to the burning surface at a rate of 10^{-3} to 1 m/s. Rates of several 100 m/s can also be achieved under certain conditions (deflagration). Detonation is chemically the same as deflagration but the chemical reaction is initiated by a shock wave which is propagated through the charge.

The burning rate depends on the prevailing pressure and differs from the pressure-independent detonation rate ($10^3 - 10^4$ m/s) by several orders of magnitude. Depending on the external conditions (confinement), chemical composition, and physical structure of the charge, a deflagration can become a detonation and vice versa.

Propellants are used whereever reproducible, time- controlled amounts of working fluid are required to propel rockets and missiles or to launch projectiles from guns (gun powder). They are also used in gas generators that are designed to jettison loads, drive turbines and pumps, actuate mechanical devices, convey liquids, or inflate balloons. The working gases of gas generators should generally have as low a temperature as possible. Gas generators are becoming increasingly important for civil applications (e.g., airbags in automobiles).

Since propellants burn without atmospheric oxygen to produce the working gas, the propellant system must contain the oxidizer required for the gas-generating reaction. The oxidizer may be available in the form of molecularly bound functional groups or in the form of discrete salts containing bound oxygen.

Propellants may exist in solid or liquid form and generally consist of several components.

The linear burning rate and its pressure dependence can be modified only very slightly by varying the chemical composition of the propellant. In order to satisfy practical requirements, the burning surface and/or the geometry of the propellant charge is therefore varied widely: this

means for rocket propellant as well as for gun propellant charges.

Solid propellants and some liquid propellants for rockets and guns may contain the fuel and oxidizer in a single phase (monopropellants). Alternatively, the liquid propellant fuel may undergo a combustion reaction with a separately added oxidizer; the combination of fuel and oxidizer (bipropellant) constitutes the propellant. Such systems involve combustion techniques similar to those used in a conventional combustion engine. The throughput can be varied by modifying the mode of injection into the combustion chamber.

The solid propellant charge and individual propellant components are subjected to mechanical stress and must have appropriate mechanical properties. With the exception of compressed powder propellants for gas generators, solid propellant charges consist of a polymeric binder matrix that may contain crystalline additives.

Single- and double-base propellants comprise plasticized nitrocellulose which may be filled with a crystalline explosive agent. Composite propellants consist of a polymeric binder that contains energetic materials and oxygen-containing salts.

Propellants also contain far more additives than explosives: stabilizers, burning moderators, energy suppliers, processing auxiliaries, etc. Previously, an explosive could be distinguished from a propellant on the basis of its chemical composition; nowadays, however, this is not always possible. For example, large proportions of high-performance explosives are found in propellant compositions, and the oxygen- containing salt ammonium perchlorate (NH_4ClO_4), commonly used in composite rocket propellants, may be found in explosive mixtures. Compositions for rocket propellants can only be distinguished from those for guns by the specific additives. There are two reasons for this. The first is the development of formulations that are particularly insensitive to external influences such as heat, impact, shock, shaped charges, or fragments (low vulnerability ammunition, LOVA). The second is the desire to obtain maximum performance.

Progressive automation of production and weapon technology within the last few decades has provided further incentives for development. Examples include the continuous production of propellants and the development of caseless ammunition, combustible casings, unit charges, and liquid propellants for guns. The use of environmentally friendly products and the possibility of recycling will also become important in the propellant sector.

2. History

The first incendiary agents were the precursors of solid propellants and were used in ancient times to attack defense fortifications and ships, and also as pyrotechnics for religious purposes.

Black powder-like compositions were discovered by Chinese alchemists in the eighth century. In the middle of the eleventh century such formulations were packed in bamboo tubes and used as rocket-propelled flame throwers. Black powder (a mixture of potassium nitrate, sulfur, and charcoal) probably reached Europe through India and Arabia by the thirteenth century: it was mentioned by Roger Bacon in 1257. Black-powder mixtures were also described by Albertus Magnus before 1280. The first drawing of a cannon operated with black powder was made by Walter de Milimete in 1326. Black powder remained the only propellant for guns and rockets for many centuries until the introduction of "smokeless powder" (plasticized nitrocellulose).

Nitrocellulose was first synthesized by Schönbein and Böttcher in 1846. In 1883 Nobel used nitroglycerine to plasticize nitrocellulose. In 1885 Vielle used an ether – alcohol mixture to produce a plasticized nitrocellulose. In 1899 Abel and Dewar used acetone as a plasticizing auxiliary. The replacement of black powder by nitrocellulose containing propellants lasted up to World War I.

In order to avoid the high barrel erosion produced by the high-performance powders, "cold powder" was developed in Germany; here, nitroglycerin was replaced by di- or triglycerine dinitrate (1935), and nitroguanidine was also added (triple-base propellant, Gudol powder 1937). "Ball powder," which can easily be metered and is suitable for use in small- caliber weapons, was developed in the United States in 1935.

Prior to the twentieth century the use of rockets propelled by black-powder charges was restricted almost exclusively to fireworks and dis-

play pyrotechnics. Few reports exist concerning the military application of solid propellant rockets. The reason for this was the short range and low accuracy of the rockets.

The development of compressed propellant charges consisting of smokeless powders began after World War I. The development of composite propellants consisting of a finely ground perchlorate- or nitrate salt that was incorporated in a polymeric binder, cast, and cured, began in 1940.

Combustible cases for larger caliber weapons were developed in the 1960s in the United States, and caseless ammunition for small caliber weapons was developed in the 1970s in the United States and Europe. Since the 1980s internationally unit charges have been produced for howitzers to automate the charging process. Since the 1970s attempts have been made to produce charges for all types of explosives (high explosives, gun propellants, rocket propellants) that display maximum insensitivity to external influences (shock, impact, temperature, etc.) while retaining their high performance (low vulnerability ammunition, LOVA). These trends, combined with efforts to produce environmentally compatible, possibly recyclable compositions, will continue.

The use of liquid propellants for rockets and missiles achieved great importance after experiments were carried out at the beginning of the twentieth century (Goddard, Ziolkowski) and before and during World War II (Oberth, Dornberger, von Braun, Nebel). This work was continued on a very large scale after 1945 in the United States and former USSR. In contrast to solid propellants, the choice of liquid propellants is still restricted to relatively few types for military application. After World War II the use of liquid propellants for guns was investigated. It remains to be seen whether these systems have any future [23–28].

3. Classification and Formulation of Propellants

Propellants are defined as substances or mixtures of substances of an explosive nature in a solid to liquid state that burn exothermically without atmospheric oxygen to form a large volume of gas. The time course of gas formation can be reproducibly predicted from the ambient pressure and the chemical composition, shape, particle size, and density of the propellant.

In order to obtain a high gas yield, the propellants must produce combustion gases that have high gas mole number, a low mean molecular mass, a high flame temperature, and a low ratio of specific heats (c_p/c_v).

Propellants are used as charges for guns, rockets, and gas generators. Solid or liquid propellant charges can be used for all three purposes. Pasty or gel-like systems have not achieved any importance.

Propellant charges serve simply to produce working gas to launch a missile from a tube or barrel or to propel rockets. In gas generators, however, they are used for a wide variety of purposes. The generated gases are used to drive pumps, empty tanks, actuate valves, bolts and separating devices, to inflate air bags, or jettison sub-systems. In contrast to propellant charges for guns and rockets, working gases for gas generators should have a medium or low temperature ($\leq 1000-1500\,^{\circ}\mathrm{C}$).

3.1. Solid Propellants

Solid propellants are used in guns, rockets, and gas generators. An extremely large variety of types is available with different forms and chemical compositions that depend on the intended use. *Single-base propellants* are based on *plasticized nitrocellulose.*

The plasticized nitrocellulose may, however, also contain an explosive plasticizer such as nitroglycerin (*double-base propellants*). Nitroguanidine may also be incorporated in the double-base powder matrix (*triple-base propellants*) in certain artillery systems that are susceptible to high barrel erosion.

In addition to nitrocellulose- containing propellant systems, a large range of *heterogeneous or composite propellants* is available. These propellants are formulated from a plastic fuel that is blended with oxygen- containing salts and/or energetic substances; they may also contain energy-rich plasticizers. The polymers themselves may have functional groups that increase the energy content of the propellant composition.

Finally, the principal constituents of double-base propellants can be combined with those of composite propellants. These combinations are termed *composite-modified double-base propellants (CMDB)* or *composite double-base propellants (CDB)*.

The most important constituents of solid propellants and their functions are listed below:

Binders (cross-linked)	polyurethane (PUR) hydroxy-terminated polybutadiene (HTPB) carboxy-terminated polybutadiene (DTPB)
Thermoplastic binder	cellulose acetate butyrate (CAB)
Energetic binders, thermoplastic	nitrocellulose (NC) poly(vinyl nitrate) (PVN)
Energetic binder, cross-linked	polyglycidylacid (GAP)
Plasticizers	triacetin dibutyl phthalate diethyl phthalate
Energetic plasticizers	nitroglycerine (NG) trimethylolethane trinitrate (TMETN) butanetriol trinitrate (BTTN) bis(2,2-dinitropropyl)acetal/formal (BTNA/F) dinitrotoluene (DNT)
Oxidizers	ammonium perchlorate (AP) ammonium nitrate (AN)
Energetic fuels	cyclotrimethylenetrinitramine (hexogen, cyclonite, RDX) cyclotetramethylenetetranitramine (octogen, homocyclonite, HMX) nitroguanidine (NQ) triaminoguanidine nitrate (TAGN)
Metallic fuel	aluminum
Ballistic modifiers for NC propellants	organic lead and/or copper salts
Ballistic modifiers for composite propellants	ferrocene derivatives, copper chromite
Stabilizers	diphenylamine nitrodiphenylamine diethyldiphenylurea (Centralite I) methyldiphenylurea (Akardite II)
Wetting agent	lecithin, polyoxyethylenesorbitantrioleate
Bonding agents	aziridine, triethanolamine
Flash reducers	potassium sulfate, potassium nitrate
Opacifier	carbon black

Details of the properties and production of the explosive components are given in [3–21], see also → Explosives.

3.1.1. Homogeneous Propellants

Single-base propellants consist mainly of plasticized nitrocellulose (nitrogen content e.g., 13.15 %). They contain plasticizers such as dibutyl phthalate and possibly additives to improve processing, suppress muzzle flash, etc. Older types of powders are processed also with dinitrotoluene. Stabilizers (e.g., diphenylamine) are added to the propellant for good storage stability. Single-base propellants are produced with maximum web thicknesses of 12 mm to facilitate solvent removal during processing with the result that they can be used only as gun propellants or in bulk powder fillings for gas generators.

Double-base propellants consist of nitrocellulose (nitrogen content 13.25 % to ca. 11.5 %) and an explosive plasticizer such as nitroglycerine. The remaining additives are similar to those used in single-base propellants. Both propellant types contain 0.5 ± 0.3 % water.

Types in which crystalline explosives such as HMX and RDX are incorporated in the double-base matrix represent a transition between double-base and composite propellants.

Triple-Base Propellants. Nitroguanidine has a relatively low flame temperature but produces a large volume of gas, and is used in "cold powders" (triple-base propellants) to reduce the flame temperature and thus protect the barrel. In these propellants nitroglycerine is replaced by explosive plasticizers with a low heat of explosion (e.g., diethyleneglycol dinitrate or butanetriol trinitrate). Examples of gun propellants are given in Table 1 and rocket propellants in Table 2.

Compositions for rockets also contain ballistic modifiers (e.g., lead salts and/or copper salts) to reduce the pressure exponent.

3.1.2. Composite Propellants

The heterogeneously formulated composite propellants consist of a polymeric binder in which crystalline oxidizers (e.g., ammonium perchlorate) and/or energy suppliers (e.g., RDX or HMX) are incorporated in amounts of up to 90 wt %. The binders are generally viscoelastic cross-linked elastomers. Compositions of composite propellants for rockets and gas generators are given in Table 3, and for LOVA guns in Table 4.

Many different types of plastics have been used but interest is now concentrated on castable

polybutadienes. Their prepolymers are terminated with carboxyl or hydroxyl groups and cross-linked with difunctional or trifunctional isocyanates in the presence of catalysts. Bonding and wetting agents and plasticizers are added to improve processing and mechanical properties. Thermoplastics (e.g., cellulose acetate butyrate) are also suitable for certain applications, in particular for gun propellants, and are compressed after incorporation of a filler [11].

The mean particle size and particle distribution of the fillers influence processing, burning behavior, mechanical properties, and shock sensitivity. Rocket propellants contain aluminum powder to increase the flame temperature, although this has the disadvantage that a large amount of smoke is produced due to formation of aluminum oxide (primary smoke). Ballistic modifiers and additives for reducing pressure oscillation are added to improve burning behavior. Composite propellants based on ammonium perchlorate release hydrogen chloride on burning, which produces intense smoke in the presence of atmospheric moisture (secondary smoke). Ammonium perchlorate is replaced by chlorine-free oxidizers (e.g., ammonium nitrate) to reduce or avoid the formation of smoke and corrosive combustion gases. Energetic substances (e.g., RDX or HMX), explosive plasticizers (e.g., nitroglycerine, BTNA/F), and energy-rich binders (e.g., GAP) are used to improve performance and/or avoid or reduce the ammonium perchlorate content. If nitrocellulose or poly(vinyl nitrate) is also added to the nonexplosive binder, composite-modified double-base propellants are obtained (CMDB, C in Table 3).

Table 2. Compositions (wt %) and performance of double-base rocket propellants

Component or property	Extruded	Cast
Nitrocellulose	48.17	49.8
(nitrogen, %)	(12.75)	(12.6)

Mean molecular mass of products	24.10	22.97
c_p/c_v	1.241	1.252

Composite propellants are particularly suitable for rockets up to very large diameters, but have also been used as insensitive LOVA gun propellants (Table 4). Corresponding developments can also be observed in the field of rocket propellants (insensitive rocket propellants, IRP). In such less- or low-sensitive propellants, nitrate esters are avoided wherever possible; instead nitramines (e.g., RDX or HMX of small grain size, $d < 10\,\mu m$) and/or nitroguanidine (spherical or high bulk density) or triaminoguanidine nitrate, are used as energy compounds [29–32].

Nitro compounds (e.g., BTNA/F) are used as explosive plasticizers. Thermoplastics (e.g., CAB) are used as binders for gun propellants. Filled viscoelastic cross-linked polymers that have been extruded and then cured may also be used as an alternative.

Performance may be improved by employing energetic binders such as GAP. Insensitive rocket propellants have similar compositions, both ammonium nitrate and ammonium perchlorate are used. The disadvantages of ammonium nitrate are its high hygroscopicity and the transformation of its crystal structure at +32.3 °C, which is accompanied by a change in density. This transformation can be displaced to higher temperatures by additives like diammine complexes of copper zinc, or nickel [33].

Propellants for larger gas generators are generally of the composite type. For small charges also single- or double-base propellants are used. Composite types have a low binder content and contain crystalline fillers (e.g., nitroguanidine, triaminoguanidine nitrate) that, on combustion, produce a large amount of gas with a relatively low flame temperature. Endothermically decomposing compounds (e.g., oxalates) are added to reduce the flame temperature. Passenger restraint systems for vehicles (e.g., air bags) generally contain sodium azide as a gas-generating charge which minimizes the concentration of carbon monoxide and carbon dioxide formed after the reaction.

3.2. Liquid Propellants [3], [15]

Liquid propellants contain the fuel and oxidizer as a single substance or mixture of substances (monopropellants), or in two separate phases (bipropellants). In contrast to solid propellants, where the solid for combustion is located in the combustion chamber, the liquid propellant is injected into the combustion chamber from a storage tank. The type of combustion and the propellant throughput is principally determined by metering. The first rockets and guns based on liquid propellants employed single substances or simple mixtures of substances. Only later did the compositions become more complex through the use of additives, which are used to modify the combustion process [34].

3.2.1. Monopropellants

Monopropellants consist of substances that already contain the oxidizer necessary for combustion (nitro compounds, nitrate esters), or of a mixture of fuel and oxidizer. These monopropellants must not react in the applied temperature range (−40 °C up to +50 °C) and must be stable on storage. Monopropellants have litte importance for rocket propulsion systems, apart from auxiliary systems (e.g., correction of satellite position).

Examples of monopropellants are 80 – 99 % *hydrogen peroxide* (which eventually decomposes, however, despite the addition of stabilizers) and *hydrazine* and its derivatives. Both compounds are injected into the combustion chamber over decomposition catalysts.

Monopropellants consisting of a mixture of components were initially used in addition to hydrogen peroxide to propel torpedoes. Examples of such mixtures are hydrazine, hydrazine nitrate, and water and compositions containing hydroxylammonium nitrate (HAN). These mixtures are known by the names Otto Fuel, Duplex, Solex, and NOS. Monopropellants were also used as propellants for guns; mixtures of nitromethane and isopropyl nitrate or methanol, as well as mixtures of hydroxylammonium nitrate and alkyl-substituted ammonium nitrate and water are of particular interest [35]. The following composition is typical:

LP 1845	63.2 % hydroxylammonium nitrate (HAN) 20.0 % triethanolammonium nitrate (TEAN) 16.8 % water

3.2.2. Bipropellants

Bipropellants consist of an oxidizer and a fuel that are injected into the combustion chamber in two separate phases. Both the oxidizer and fuel may consist of more than one component.

Conventional systems for rocket propulsion consist of hydrogen peroxide, concentrated nitric acid, nitrogen dioxide, or liquid oxygen as oxidizer, and hydrocarbons (e.g., rocket propellant, RP 1; jet propellant, JP-5), alcohols, amines, hydrazines, and alkyl derivatives as fuel. Liquid fluorine or a mixture of fluorine and oxygen (FLOX) and liquid hydrogen are also used in

aerospace applications to improve performance. Some propellant combinations are hypergolic (i.e., the fuel and oxidizer ignite spontaneously on contact). Examples are concentrated nitric acid and hydrazine or alkyl derivatives. This hypergolic behavior is exploited in guns, where the propellant combination ignites immediately when injected into the combustion chamber; an example of such a propellant is concentrated nitric acid and monomethyl hydrazine (MMH) or triethanolamine.

4. Reactions and Properties

Propellants have to satisfy various criteria and must also have specific properties, depend-ing on their use. When choosing and developing a propellant its properties must therefore be matched against one another to achieve the best solution. This requires interdisciplinary cooperation between the system developer and propellant manufacturer. Factors that have to be observed when choosing a propellant are listed below:

Ignition conditions
Burning rate (depending on pressure and temperature)
Performance
Internal ballistic behavior (combustion instability and pressure irregularities, pressure – time curve)
Density and bulk density
Chemical stability and compatibility
Long storage behavior – service life
Mechanical properties (depending on temperature and stress rate)
Deflagration to detonation behavior
Sensitivity and vulnerability
Manufacturing characteristics (availability, cost, hazards etc.)
Rocket exhaust smoke
Gun smoke and flash

4.1. Combustion Process [12], [36–38]

The burning behavior of a solid propellant depends on its composition, pressure, propellant temperature, and on the characteristics of the flow field. The propellant burns in parallel layers vertically to the burning surface, provided that the combustion gases can escape unimpeded. The mass flow rate depends on the amount of heat produced during combustion and its feedback to the burning surface. Ignition is effected by heating the propellant surface above the decomposition temperature with hot gases, hot particles, or lasers.

Many combustion models exist for different compositions and pressure ranges. In practice the following equations are used:
For propellants in guns ($p > 200$ kPa)

$$r = a + bp$$

and for rockets ($p < 30$ kPa)

$$r = cp^n$$

where

r = linear burning rate
p = pressure
a, b, c = temperature-dependent constants
n = pressure exponent

The gaseous combustion zone above the burning surface constitutes the heat source for propellant decomposition. A rise in pressure compresses the combustion zone, thus increasing the heat feedback to the surface and producing a higher burning rate. A higher propellant temperature also increases the burning rate because less heat is then required to heat up the surface. At higher temperatures, higher pressures are therefore obtained in the gun or rocket combustion chamber.

Burning mechanisms differ according to the composition of the propellant. With *homogeneous* (single- and double-base) propellants the nitrate ester decomposes near the propellant surface (fizz zone) at ca. 600 K (Fig. 1). The primary products react in the nonluminous dark zone at ca. 1050 – 1750 K, which disappears at higher pressures. Further reaction up to thermodynamic equilibrium then occurs in the overlying flame zone (1650 – 2200 K).

Figure 1. Diagram of the flame structure of a double-base propellant [36]

In the pressure range ca. 7 – 20 kPa, the use of burning modifiers consisting of lead and/or copper salts of aliphatic and aromatic acids in NC- containing propellants may result in a pressure-independent burning rate (plateau $n = 0$) or a reduction in the rate due to a pressure rise (mesa effect, n becomes negative) (Fig. 2). In general the pressure exponent in rockets should not exceed $n = 0.6$.

Nitramines such as RDX or HMX melt before or during decomposition, depending on the heating rate. The decomposition products then

react like the other combustion products in the zones described above [39].

Figure 2. Burning behavior in solid, double-base propellants
a) Propellant without catalyst; b) Plateau propellant; c) Mesa propellantPropellant temperatures are indicated

Oxygen- containing salts, polymeric binders, and metal powders (aluminum) exhibit different combustion mechanisms, which can also change with pressure and temperature [40], [41]. The oxygen-rich gases of the decomposing oxygen-containing salt and the pyrolysis products of the organic binder produce a diffusion flame. The grain size of the ammonium perchlorate greatly influences the burning rate: the smaller the grain size the higher the burning rate. Burning modifiers (e.g., copper chromite) also increase the burning rate (Fig. 3). The grain size of ammonium nitrate has far less influence; these propellants have a relatively low burning rate, which can be increased by adding similar burning modifiers like ammonium dichromate. Oxidation of the metal powder occurs a long way from the burning surface and has only a slight effect on the burning rate. The small metal particles often agglomerate to form larger aggregates.

In *liquid monopropellants* vaporization and decomposition of the liquid occur on the droplet surface and depend on the composition and heating rate. Combustion follows in the gaseous phase. With *bipropellants* a diffusion flame is formed between the oxidizer and fuel.

4.2. Propellant Performance

The performance of a propellant is determined by its composition, its reaction products, and the difference between the heat of formation of the reactants before and after the reaction. The most important thermodynamic features of the combustion products are the flame temperature, gas volume, heat capacity, ratio of specific heats (c_p/c_v), and, where appropriate, the covolume of the gases at high pressures.

Figure 3. Burning rate range for polybutadiene propellants [16]
a) AP propellants with burning rate modifiers like metal oxides; b) AP propellant with different particle size; c) Propellant with mixed AP and AN oxidizers

Since the early 1970s computer programs have been developed to calculate the performance of gun and rocket propellants, they generally have an accuracy of 1 – 2 % [42], [43–45]. Differences between the results of the programs are generally attributed to different thermodynamic input data.

The specific energy or force f (in $\mathrm{m \cdot t\,kg^{-1}}$ or J/g) is derived from the equation of state for gases ($f = pV = nRT$) and is used as the performance parameter for gun propellants, where

p = pressure
V = volume
n = number of moles of gas
R = universal gas constant
T = explosion temperature

Since propellant powders in a gun at virtually constant volume and varying pressure (≤ 600 kPa) burn at temperatures up to 4000 K, the calculation requires an equation of state that takes into account the behavior of the gases at high densities (virial equation) [43–45].

The computer programs also provide information on the heat of explosion, explosion temperature, average molecular mass of the explosion products, total mole number, composition of the explosion gases, specific heat ratio (c_p/c_v), and covolumes. Examples of performance data of gun propellants are given in Tables 1 and 4.

The most important performance parameter of rocket propellants is the specific impulse I_s:

$$I_s = \frac{\bar{F}t}{w} \text{ in Ns/kg}$$

where

$\bar{F}$ = average thrust
t = burning time
w = weight of propellant

As the following equation shows, the specific impulse depends on the flame temperature in the chamber T_c, the average molecular mass of the flame gases $\bar{m}$, the specific heat ratio $k = c_p/c_v$, and the pressure expansion ratio p_c/p_e

$$I_s = \sqrt{\frac{2}{g} \cdot \frac{RT_c}{\bar{m}} \cdot \frac{k}{k-1} \left[1 - \frac{p_e^{(k-1)/k}}{p_c}\right]} \text{ Ns/kg}$$

where g is the acceleration due to gravity, p_c is the chamber pressure and p_e is the pressure at the nozzle end.

In contrast to gun propellants, rocket propellants generally burn at a uniform pressure. The specific impulse is often given at an expansion ratio of 70: 1, a distinction is made as to whether the combustion gases at the nozzle end are in equilibrium $I_{s,\,equil}$ or in a frozen state $I_{s,\,froz}$.

As well as the specific impulse the following information can be obtained from the computer programs:

Chamber temperature (adiabatic flame temperature)
Temperature of exit gas (equilibrium or frozen)
Composition of the burnt gases
Average molecular mass of the burnt gases
Total mole number of the burnt gases
Ratio of specific heats c_p/c_v

Since, in practice, the gas jet does not expand fully due to the restricted nozzle dimensions, a difference of up to several percent is found between the theoretical and experimentally determined specific impulse. Aluminum oxide occurs as condensed particles in the combustion jet and these particles often do not reach the gas flow rate. The difference between theory and practice is thus even greater in aluminum- containing propellants.

The combustion gases only reach equilibrium at the nozzle end in rockets with very large diameters. Examples of rocket-propellant performance data are shown in Tables 2 and 3.

Experiments in standard combustion chambers are carried out on a kilogram scale to determine the performance, burning behavior, and chamber pressure at different "Klemmung" (ratio of the burning surface area of the propellant charge to the nozzle throat area).

Since the volume of the loading chamber of a gun and the volume of a rocket combustion chamber are restricted, a charge with a propellant of a high density has advantages as regards performance. The velocity of a rocket V_b on completion of burning is also influenced by the ratio of the rocket mass at the start and completion of burning. For vertical liftoff the following equation applies:

$$V_b = \bar{V}_g \ln \frac{m_a}{m_e} - gt$$

where

V_g = velocity of the combustion gases
m_a = rocket mass at start
m_e = rocket mass at completion of burning
g = acceleration due to gravity
t = burning time

The densities of single- and double-base propellants are 1.54 – 1.64 g/cm^3. Composite propellants may have densities as high as 1.76 g/cm^3, particularly if they contain aluminum powder.

4.3. Mechanical Properties

Propellant charges are subjected to mechanical stresses that depend on their shape, size and the form in which they are used. Since propellants mainly consist of polymers, their mechanical properties also depend on the temperature and the stress rate. According to the superposition principle, the low-temperature behavior of the embrittlement, tensile strength, and elongation is nearly the same as that of propellants at room temperature but at high stress rates [46–48].

Gun Propellants. In guns the propellant powders are subjected to the force of the pressure wave in the powder bed. In extreme cases they are thrown against the base of the projectile during ignition. This leads to the danger of embrittlement, especially at low temperature with double- and triple-base propellants. Embrittlement results in an uncontrolled rise in pressure in the lower temperature range.

Rocket Propellants. The mechanical properties of rocket propellants are of greater importance. The thermoplastic double-base propellants generally have a high tensile strength and a relatively low elongation at break. They are therefore used as cartridge case propellant charges. The temperature range is limited due to embrittlement in the low temperature range (ca. −30 °C) and softening above +70 °C.

Viscoelastic composite propellants generally have a high elongation at break and a relatively low tensile strength. Composite propellants are therefore almost always used as case-bonded propellants, the large expansion capacity of the propellant absorbs the chamber movement as a result of temperature cycling. The tensile strength needs only be sufficiently large to ensure stability of the propellant under load. The larger the diameter and length of the propellant charge, the greater must be its elongation at break.

During the service life of a solid propellant the mechanical properties change in varying degrees. With composite propellants the elongation at break can deteriorate resulting in embrittlement caused by postcuring effects. Softening can also occur as a result of depolymerization, and leads to deterioration of the tensile strength [48].

The mechanical properties are also greatly affected by adhesion between the filler and binder. Moisture, frequent temperature variations, and vibration can cause dewetting of the filler from the binder, resulting in a decrease of the mechanical properties. In nitrocellulose the mean molecular weight decreases during aging, which likewise negatively affects the mechanical properties [49].

Surfaces of rocket propellants that are not meant to burn for internal ballistic reasons are provided with firmly adhering insulation layers made of polymers that are compatible with the propellant (e.g., ethylcellulose for double-base propellants and PVC or HTPB for composite propellants). The insulation layers may also contain inert fillers and plasticizers. The mechanical properties of the propellant and/or insulation can also change due to mutual migration of their constituents, and may result in malfunctions.

4.4. Chemical Stability

Nitrate esters decompose to form nitrogen oxides which provide the decomposition of ester groups (autocatalysis). This process is exothermic and can lead to self-ignition of the propellant. Stabilizers (e.g., substituted diphenylamines, ureas, or urethanes) are added to inhibit this reaction. Examples include diphenylamine, nitrodiphenylamine, and diphenylureas (Centralite, Akardite) [50–52].

The stabilizers trap the released nitrogen oxides to form polynitro compounds. The final stability of such a propellant is measured by the residual capacities of the stabilizers to trap nitrogen oxides. The process is temperature dependent and obeys the Arrhenius equation. Information of the service life of a propellant at normal temperature can thus be obtained from stability testing at elevated temperature.

Besides NO_x also N_2O, CO, CO_2 and H_2O may be formed during the aging process by re-

action of NO_x with the remaining reactants. In large propellant charges these gases lead to crack formation. Especially CO_2 may also accumulate underneath the insulation and detach it from the propellant surface.

The conventional composite propellants containing ammonium perchlorate are extremely stable. Chemical reactions involving the binder affect the mechanical properties. Nitramines and plasticizers containing nitro groups are also more stable than nitrate esters.

Hot-storage tests are used to check the chemical stability: samples of propellants are stored at 65.5 – 132 °C and the weight loss or release of gasis measured. Propellants that come into contact with other materials (insulation materials, liners, metal parts, etc.) are subjected to compatibility testing, i.e. the propellant is investigated to determine whether it reacts with the other material at elevated temperature (release of gas).

4.5. Service Life

The service life of a propellant ends when the reproducibility of performance and function can no longer be guaranteed within the prescribed limits.

The duration of the service life depends on the chemical composition, size of the propellant charge, type of use, conditions of storage and use (storage temperature, temperature fluctuations, moisture, mechanical stress, etc.), and the prescribed operational conditions.

The service life of gun propellants may be assumed to be about 30 years or even higher under good storage conditions and with very stable powders. Rocket propellants generally have a shorter service life, in some cases only 12 years [53].

4.6. Sensitivity and Vulnerability

Sensitivity. As in the case of high explosives, propellants are also screened to investigate their handling safety. Various methods and equipment are used to test the sensitivity with respect to impact, friction, electrostatic discharge, heat, and flame. Standard national test regulations exist for the certification of propellants and obtaining permission for transportation [54–57].

In 1987 the United Nations Committee of Experts on the Transport of Dangerous Goods issued recommendations for tests and criteria and has classified dangerous goods in nine classes [58]. Class 1 includes five explosive divisions

1.1) Substances and articles which have a mass explosion hazard
1.2) Substances and articles which have a projection hazard but not a mass explosion hazard
1.3) Substances and articles which have a minor blast hazard or a minor projection hazard or both, but not a mass explosion hazard
1.4) Substances and articles which present no significant hazard
1.5) Very insensitive substances which have a mass explosion hazard but are so insensitive that there is very little probability of initiation or of transition from burning to detonation under normal conditions of transport. As a minimum requirement they must not explode in the external fire test.

Handling and transport regulations are governed by the classification according to these five subdivisions. In some countries these subdivisions also have consequences for munition storage regulations.

The United Nations scheme provides for six test series which can also be applied to liquid propellants (monopropellants). The following parameters are tested:

1) Detonative shock under confinement
2) Intensive heat (fast cook-off)
3) Impact and friction
4) Thermal stability
5) Ignition
6) Free-fall impact of a test unit
7) Shock from a detonator cap
8) Transition from deflagration to detonation
9) Exposure of substance in packing to an external fire

With an additional Test Series 7, articles of Division 1.5 and extremely insensitive detonating substances (EIDS) are identified and specified precisely. For example, for EIDS the following are additionally specified:

1) Threshold for propagation of steady-state detonation conditions = Critical Diameter (confined and unconfined)

2) Detonative shock under confinement = EIDS GAP Test
3) Relative behavior of high explosive loads in projectiles and fired against a target = Susan Test
4) Mechanical behavior of a compact high explosive under a large impact (velocity of pieces = 150 m/s) = Friability Test
5) Response of an EIDS to kinetic energy associated with impact and penetration = Bullet Impact Test
6) Reaction to a gradually increasing thermal environment (3 K/h) = Slow Cook-Off Test

Vulnerability. The vulnerability of munition depends on the behavior of its explosive components with respect to external influences. These may vary in nature and intensity according to the use of the munition and the expected military threat. The inherent vulnerability is a combination of

1) The susceptibility of munition to initiate an unintentional reaction (i.e., its sensitivity)
2) The violence of such a reaction (i.e., its explosiveness) caused by accident (e.g., shock, impact), environmental stress factors (e.g., aerodynamic heating, electrostatic charging), and enemy action (e.g.,fragmentation shock).

The vulnerability of munition can be improved by modifying munition construction, implementing appropriate mechanical measures, and using insensitive energetic materials such as insensitive high explosive (IHE), insensitive gun propellants (LOVA), and insensitive rocket propellants (IRP). These insensitive energetic materials should react reliably on demand and fulfill performance requirements. Regardless of whether such materials are confined in munition or not, undesirable external influences caused by heat, shock, fragmentation projectiles, impact, friction, and electrostatic discharge should not lead to violent reactions that produce hazardous fragments or blast waves.

In order to check the vulnerability of gun and rocket propellant charges, the tests of the abovementioned Test Series 7 (Division 1.5) are used to the specific threat.

5. Uses

5.1. Gun Propellants

5.1.1. Solid Propellants

The Firing Process. In the firing process the propellant charge is ignited by a pyrotechnic device. Solid propellants for guns are also known as gun powder. Ignition is effected by hot gases, and is often assisted by the emission of hot particles. Lasers may be also used in future. The objective is to initiate ignition simultaneously over the whole surface of the propellant charge. Ignition lasts between < 1 ms and several 10 ms depending on the caliber size. The propellant charge then reacts to form hot gases, and the generated gas pressure ejects the projectile with increasing velocity from the barrel. Only 30 –40 % of the chemical energy is converted into kinetic energy to propel the projectile; 40 – 50 % is converted into kinetic energy of the gases or remains as heat in the gases; a further 20 – 25 % heats the barrel, case, and projectile. The pressure falls due to the energy losses of the gases and the increase in volume as a result of movement of the projectile. Thus, the gas pressure usually reaches a maximum value as a result of combustion of the propellant charge, and then falls. The propulsion process generally lasts < 10 ms, and accelerations of more than 10^5 g are produced. Muzzle velocities may reach 2200 m/s with high-performance artillery, at maximum gas pressures of more than 700 kPa [59], [60].

The firing process involves not only thermodynamic and gas dynamic processes, but also the reaction kinetics of the decomposition products of the propellant. The firing process can be simulated with internal ballistic computer models.

The gas pressure curve produced on burning the powder can be influenced by the following parameters:

1) Linear burning rate r of the propellant.
2) Treatment of the powder grains. The surface of the powder grain is modified so that it burns more quickly or more slowly than the underlying layers; treatment with plasticizers (e.g., camphor, dibutyl phthalate) produces an initially slower burning rate (progressive behavior). Incorporation of salts

(potassium nitrate) into the powder grain and subsequent dissolution yield a porous powder structure with a large, initial rise in pressure (manoeuver powder).

3) Loading density Δ of the propellant

$$\Delta = \frac{\text{Propellant weight}}{\text{Combustion volume}}\,\text{g/cm}^3$$

The loading density is in general between 0.1 (mortars) and 1.1 g/cm^3.

4) Total free propellant surface area.
5) Shape of the propellant particle.

The quotient of the powder area at time z (A_z) and the initial area A_a is termed the form function $f = A_z/A_a$. The dynamic vivacity is defined as

$$L = \frac{\dot{p}}{p_m \cdot p} \text{ where } p_m = \text{maximum pressure.}$$

Gun Barrel Erosion. Chemical and physical interactions between the high-velocity, hot combustion gases and the wall of the barrel result in barrel wear due to erosion. These phenomena occur particularly in high-performance weapons and powders with high combustion temperatures. Barrel erosion and wear can be reduced by using additives (e.g., titanium dioxide or talcum). To avoid erosion the combustion temperature can be lowered by adding nitroguanidine and replacing nitroglycerine by less energetic explosive plasticizers (cold powders) [59].

Muzzle Flash. Only substoichiometric amounts of oxygen are available to react with the propellant charge powders. Combustible gases (CO, CH_4, etc.) therefore leave the muzzle during firing, which can mix with the air and ignite (muzzle flash). This can be suppressed by adding appropriate compounds (e.g., K_2SO_4 or KNO_3) to the propellant [61].

Charge Technology. The propellant charge can be combined with the projectile to form a munition unit (cartridge munition) which is packed in the loading chamber. Alternatively, the propellant charge is introduced separately into the weapon in powder bags in some cases enclosed in a metal cartridge. Gun propellants may be classified according to the shapes into which they are formed: long tubes (perforated or unperforated), strips, sticks (slotted or unslotted), short-cut perforated tubes, short-cut multiperforated tubes, flakes, and ball powder [62], [63], [64].

Types of Ammunition. Since the early 1980s *caseless ammunition* has been developed for small-caliber weapons. The advantage of this type of ammunition is a short, compact cartridge in which an empty case no longer has to be ejected after firing. It consists of a porous powder body which partially or completely encloses the projectile (Fig. 4).

Figure 4. Caseless ammunition (4.73 mm X 33, Dynamit Nobel) for the G11 rifle

Ignition is initiated by a combustible cap. The powder charge often contains a small priming charge that comminutes the propellant charge into small elements during ignition. The propellant charge body is also provided with a combustible protective layer to prevent ignition outside the weapon. Unintentional ignition of caseless ammunition on contact with the hot walls of the loading chamber after previous firing (cook off) may be a problem. Solid propellant compositions having a high thermal stability are therefore used. An example of such a high ignition temperature propellant (HITP) is a finely crystalline, plastic-bonded nitramine (e.g., HMX) [65].

The desire to save material and avoid having to eject powder cartridges has led to the development of *combustible cases* for ammunition for large-caliber weapons. The case consists of a mechanically and thermally stable material like

condensed cellulose fibers or a polymeric material which burns together with the powder charge under the high pressure existing in the weapon without forming a residue. The outer wall of the case also has a protective layer to prevent ignition outside the weapon.

In the case of ammunition that is charged separately, the cartridge contains several partial charges for the different firing zones. *Modular charges* have been developed to reduce the number of partial charges. The ultimate aim is to use only one universal partial charge which can be snapped together to build up the complete charge and provide the required range.

The "unicharge" is packed in a rigid combustible cartridge case which contains its own priming charge. The tubular unicharges are closed at both ends to protect the igniter and propellant from the environment. To ensure that the flame spreads along the full length of the unicharge, barriers are ruptured when the charges are combined.

5.1.2. Liquid Propellants

Spurred on by the rapid development of rocket technology using liquid propellants, experiments began soon after the end of World War II to see whether liquid propellants could also be used for guns. This concept promised considerable advantages:

1) Improvement of specific performance
2) Optimization of the pressure – time curve
3) Avoidance of a cartridge
4) Less space required for the ammunition and thus better space utilization
5) Adjustment of the firing range by controlled metering of the liquids
6) Increase in the firing rate (cadence)
7) Lower propellant costs

This concept also opens up potential solutions for automating many aspects of artillery technology.

Disadvantages were also anticipated, for example a complicated conveyance and metering system, corrosion and handling problems, and an internal ballistics behavior that was largely unknown.

After 45 years of international development, it was found that such systems are feasible [66]. Two systems exist:

1) Bulk-loaded propellant guns (BLPG)
2) Regenerative liquid propellant guns (RLPG)

Figure 5. Schematic of a regenerative test fixture for a liquid-propellant gun chamber [59]
a) Propellant fill port; b) Ignition port; c) Injection orifices; d) Propellant reservoir; e) Barrel; f) Combustion chamber; g) Chamber; h) Regenerative piston; i) Seals; j) Breech plug

These systems can be operated with monopropellants (see Section 3.2.1), or bipropellants (see Section 3.2.2).

In BLPG using monopropellants, the loading chamber behind the projectile is filled with the liquid propellant (charging density 1 – 1.45 g/cm^3). Ignition is produced with a pyrotechnic device or submerged electric spark. Although the concept appears extremely simple, the internal ballistics are extremely complex and difficult to control. For example the energy and geometry of the igniter as well as the geometry of the chamber greatly influence the reaction of the liquid. The use of non-hypergolic bipropellants in BLPG has not been investigated in detail since it is even more difficult to control.

With RLPG the combustion process can be controlled more easily. The liquid is injected into the chamber as a result of gas pressure. A model of a monopropellant regenerative test fixture is shown in Figure 5 [59].

The regenerative system can also be used for bipropellants, both liquids are injected separately into the chamber. Such a system is more complex but offers better performance. The advantages of a hypergolic combination (e.g., nitric acid – triethylamine) can be exploited.

Gun systems with liquid propellants are unsuitable for small- caliber weapons. They are becoming increasingly important for machine guns (> ca. 30 mm caliber), but especially for cannons, howitzers and mortars. The regenerative

system is preferred to bulk loading. The suppression of pressure oscillations during combustion poses a special problem, monopropellants have a greater tendency than bipropellants to exhibit such oscillations.

5.2. Rocket Propellants

5.2.1. Solid Propellants

Solid propellants are used in rocket motors and ram jet engines. Rocket motors designed for solid propellants are relatively simple and generally contain no movable parts. Depending on the intended application, they operate at 2 – 50 kPa with burning times of fractions of a second up to several minutes. They are used for propelling projectiles or as a starting aid for aircraft [10], [13], [18]. Up to 70 % of the chemical energy of the propellant is converted into kinetic energy of the exhaust gas jet, of this no more than 70 % can be utilized for propulsion.

Hybrid propellants for rocket motors consist of a liquid and solid propellant, for example a liquid oxidizer that is injected into a combustion chamber containing a fuel grain.

Propellants for ram jet engines produce a combustion gas that is highly deficient in oxygen, and which can be almost completely burnt with the air of the ram jet engine.

The thrust program of a solid propellant motor is fixed and depends on the mission to be fulfilled by the rocket; it is mainly determined by the burning rate of the propellant as a function of pressure and temperature and by the propellant charge configuration. Examples of configurations are shown in Figure 6.

Depending on the physical and mechanical properties of the propellant, the charge may be free-standing (ends are supported against the chamber wall by mountings) or securely fixed to the chamber wall over its entire length (case-bonded grains). The first type include charges with a relatively high tensile strength and low elongation, and are mainly double-base propellants. Composite types (i.e., compositions with rubber-elastic properties) can follow the thermal expansion of the chamber wall and may therefore be securely joined to the latter via an insulation layer or liner. Such charges are "internal burners", which means that the flame reaches the chamber wall only at the end of the combustion.

Propellant charge surfaces that are not intended to burn are covered by an insulation that adheres firmly to the propellant charge and should have similar mechanical properties. These insulations consist of polymers, which may be filled with inert materials. Secure adhesion of the insulation to the propellant charge surface while the rocket motor is in use is important.

The propellant charge can be ignited from the nozzle side or the opposite side. Sealing of the nozzle ensures a rapid rise in pressure during ignition, excludes environmental climatic influences, and ensures safer handling.

Burning of the propellant in the combustion chamber is accompanied by phenomena that are influenced by the propellant, its burning surface, the combustion products, and the design of the propellant charge and combustion chamber. *Erosive burning* denotes the increase in burning rate caused by the flow of product gases across the burning surface of the propellant. The rate may more than double, especially at high gas flow rates. Increased erosion changes the pressure – time curve and may cause failure of the rocket motor [67].

Combustion instabilities may be either acoustic or irregular. In acoustic instability the pressure in the combustion chamber oscillates at high or low frequency. The burning zone acts as an amplifier, the propellant charge and thermal losses as a damping element, and the combustion products as the oscillating medium. The oscillation frequency is related to the dimensions of the combustion chamber.

Irregular instabilities may take the form of pressure variations or a sudden increase and decrease of the combustion chamber pressure caused by specific properties of the propellant [68].

5.2.2. Liquid Propellants

In rocket combustion chambers with a solid propellant charge, the nature and configuration of the charge predetermine the thrust program of the rocket. In rocket motors with a liquid propulsion system, however, the thrust can be varied within wide limits during the mission.

Figure 6. Different grain configurations and their burning characteristics

The propulsion unit consists of a combustion chamber and a nozzle (which are regeneratively cooled in larger rockets), complex injection devices, conveying devices with regulating units, pumps, turbines, and the propellant containers. In smaller rockets the propellants are conveyed to the combustion chamber by the action of pressure on the storage containers.

Monopropellants are injected into the combustion chamber either directly or over a catalyst bed. Rocket motors with monopropellants are normally used as pulsed propulsion units for controlling the position of satellites or rockets. Bipropellants are injected separately into the combustion chamber with a separate conveying system. The injectors are designed so that rapid compression mixing can take place. Ignition is effected either hypergolically or by a pyrotechnic or electric device. The ignition must be accurately coordinated with the injection process to avoid excess pressure in the ignition phase. The few liquid propellant rockets still used for military purposes are already with supplied propellants. Most liquid propellant rockets for civil purposes (space probes and rockets) are fuelled just before the start of flight. Fuelling is extremely slow, particularly with cryogenic propellants, and accordingly the countdown of a large rocket with a liquid propulsion unit lasts many hours [15].

5.3. Propellants for Gas Generators

The function of gas generators is to produce working gases. The charges are of different design that depend on the desired function time and required gas volume. They may be in the form of granules, tablets, or configurations similar to the propellant charges of projectiles or rockets. The gases that are produced activate mechanical devices and inflate or empty vessels and containers.

The combustion charges should therefore produce noncorrosive, low-temperature gases. For reasons of safety and a defined action time, the combustion charges are accommodated in vessels provided with rupture membranes. A typical example is the automobile airbag [69].

Gas generators are used to fill the low-pressure region formed at the rear of a flying projectile and thus by reducing the drag the range can be extended by ca. 20 % (*base bleed*). The mechanical properties of the charges must be able to withstand the high acceleration produced during launching [70], [71].

6. Production

Propellants are energetic materials and have to be handled, manufactured, and transported in such a way as to minimize the risk of accidents. In order to reduce the risk (defined as the probability of an accident times the extent of the damage), a series of independent safety measures are adopted during production and a maximum amount of explosives that can be handled by a defined workforce is specified. Where possible the individual process steps are carried out in special buildings or are separated from one another to minimize the risk of secondary explosions. A remote control is necessary with all processes in which explosive materials are involved and exposed to thermal or mechanical stresses. The manufacturer has to observe safety regulations, this is confirmed and monitored by appropriate safety authorities. A trend towards continuous processing (small amounts of explosive in the individual process steps) can be seen because this improves productivity and reproducibility, and also reduces the risk of accidents. Since the compositions and production processes for gun and rocket solid propellants exhibit many similarities, both types will be discussed jointly. They are classified according to Chapter 3 [3], [5], [7], [42].

Liquid propellants are chemical compounds or their mixtures that are produced by the chemical industry; they do not require special manufacturing processes.

The production of small- caliber ammunition for sport and hunting guns has remained relatively constant over the past few decades. A wide variety of ammunition is produced, largely by private companies. Research, development, and production for military purposes are carried out by government organizations and private companies, in some countries there is a trend toward privatization. The same applies to military rocket propellants. Propellants for aerospace rockets are mainly supplied by producers for the military sector.

Recent world political developments have led to a large reduction of military engineering activities, production is estimated to have declined by 25 – 40 %.

6.1. Homogeneous Propellants

6.1.1. Single-Base Propellants

Batch Solvent Process. This process involves the plasticization of fibrous nitrocellulose by means of solvents (ether – alcohol or acetone) [72–74] which subsequently have to be removed. The process is therefore suitable only for small powder grains with maximum web thickness of at most 13 mm.

The water-wet nitrocellulose (30 %) in the form of a mixed material (e.g., gun cotton containing 13.4 % N and collodium wool containing 12.5 % N in an 80: 20 ratio) or a uniform nitrocellulose (e.g., 12.8 % N) is subjected to displacement with 95 % ethanol in presses or centrifuges. The compressed nitrocellulose is broken up, sieved, and kneaded in a water-jacketed bladed mixer with the addition of appropriate stabilizers, plasticizers, and solvents. The plastic material is then shaped into strips, noodles, or tubes by extruders or pot presses with suitably formed dies. The strips etc. are cut to the desired lengths, graphitized in drums to prevent electrostatic charging, and dried to remove residual solvent. Drying is accompanied by shrinkage of the powder grains. Residual solvent can also be removed by intermediate soaking in hot water. Finally, surface treatment with plasticizers to slow the burning rate at the beginning of the grain combustion can be carried out in drums depending on the desired internal ballistic properties. The individual batches are mixed to obtain lots with reproducible ballistic properties.

Continuous Solvent Process. Single-base propellants can be manufactured continuously

[75]. The alcohol-moist nitrocellulose and additives are fed on a conveyor belt equipped with a continuous weigh-belt into a compounder consisting of a horizontal rotary plow. Solvent is added to form a homogeneous mass, which is then fed to a temperature- controlled screw mixer. The compacted paste is extruded through a die plate and cut into granules. These granules are then fed continuously into an extruder and the extrudate is cut into granules by rotating knives. The solvent is then removed as described above. The continuous mixing and kneading machines and the extruder are all temperature-controlled. On account of the complexity of the machinery and comprehensive control and monitoring system, such a plant is generally only used for large-scale production.

6.1.2. Double- and Multibase Propellants

Solvent Process. Double-base propellants for gun propellant charges can be manufactured by the processes used for single-base propellants [76]. The nitroglycerine is added in the form of a nitrocellulose – nitroglycerine powder preconcentrate or is mixed with the solvent. Propellants containing a small proportion of nitroglycerine are manufactured in this way because the gelatinization effect of the nitroglycerine in a low percentage is insufficient to form a homogeneous material. Triple-base propellants also contain nitroguanidine of generally very small grain size ($d_m = 4\ \mu m$) [77] and can likewise be manufactured by the solvent process. Nitroguanidine has a high gas yield at relatively low combustion temperatures. In order to reduce the combustion temperature of the propellant still further in order to reduce barrel erosion, the combustion temperature of the charge can be lowered by replacing nitroglycerine by less energetic plasticizers such as diglycol dinitrate, 1,2,4-butanetriol trinitrate, or metriol trinitrate.

Solventless Process. Roll and Extrusion Process. The use of solvents can be avoided by plas-ticizing nitrocelluloses with a lower nitrogen content (11.8 – 12.7 % N) with nitroglycerine or other liquid nitrate esters to form a homogeneous colloid. This widespread process is suitable for manufacturing gun- and rocket propellant charges. It has the advantage that the removal of solvent is avoided, larger propellant charges can therefore be produced.

Nitrocellulose and additives are suspended in water at 50 °C, and nitroglycerine and other plasticizers are added. The nitroglycerine is adsorbed by the nitrocellulose and the water is removed in a centrifuge to lower its concentration to 15 –30 %. The thoroughly mixed crude material is freed from residual water by means of heated rolls (95 °C) under friction, and is gelatinized. The homogeneous gelled material then passed between rolls running in the same direction at 60 °C to form carpet rolls of uniform thickness. The carpet rolls are cut into sections, laid together, and fed to an extrusion press where they are pressed at 70 – 100 °C and up to ca. 100 MPa. The feed rate is some centimeters per minute.

Generally powder strands with a diameter between one and up to 200 mm can be produced. The propellant strands are cut into the desired length. Rocket propellant charges are stored under temperature- controlled conditions to eliminate stresses and are checked by X-ray examination for cracks or voids.

This batch process has the usual disadvantages such as inadequate reproducibility and quality assurance. The roll process is labor-intensive and environmentally harmful. Extruding large quantities of propellant material in one batch involves a high safety risk. Individual work stages have therefore been improved (e.g., by remote- controlled operation during rolling). The use of shearing rolls permits continuous operation [78].

Screw Extrusion Process. In order to avoid the disadvantages associated with rolling and extrusion batch by batch in the mid 1960s Dynamit AG began to develop a continuous, fully automatic screw extrusion process for rocket propellants.

The crude material, which contains 25 % water, is fed automatically and continuously to twin-disk mixing devices. After sufficient dewatering and preplasticization, granules are produced in a screw extruder. Residual moisture is removed and the granules are shaped in a twin-screw extruder. Internal propellant with an external charge diameter of 300 mm were produced with this equipment [79], [80].

In the late 1970s twin-screw extruders were used for mixing, dewatering, plasticization, and shaping in the continuous manufacture of double- and triple-base gun propellants [81], [82].

Ball Powder Process. This process was developed in the United States at the end of World War II and yields spherical powder (ball powder) with a diameter of 0.4 – 1 mm. It can be used to recycle nitrocellulose from types of powder that are no longer required. Since the process is carried out in the presence of water, it is relatively safe. Ball powder is mainly used in small- caliber munition because it permits a high packing density and automatic cartridge filling [83–85].

Nitrocellulose is dispersed in warm water in a stirrer, after adding ethylacetate. The solvent evaporates on raising the temperature, and the nitrocellulose precipitates as small droplets. After adding a protective colloid, the solvent is completely evaporated. The solid nitrocellulose balls are then discharged into a washing tank. The balls are washed with water, screened, and passed to a coating tank where they may be enriched with nitroglycerine. Surface treatment with a plasticizer also takes place in the coating tank. Rolled ball powder is used in shotgun cartridges.

Fluid ball powder consists of small nitrocellulose balls with diameters of 0.05 – 0.15 mm. It is produced similarly but with a greater stirring energy, and is used as a starting material for the manufacture of double-base rocket solid propellants by the slurry process. The ball powder may also be treated with nitroglycerine [3], [86].

Casting process. The casting or Steinberger process (Hercules) allows the production of double- and multibase rocket propellants charges with large diameters [86], [87]. A single- or double-base granulate (casting powder, diameter ca. 1 mm) containing the solid additives (e.g., burning modifiers, stabilizers) is first prepared by a solvent process similar to that used for gun propellants. Oxygen- containing salts (e.g., ammonium perchlorate), aluminum powder, and explosives (e.g., RDX or HMX) can also be incorporated to improve the performance. Nitrocellulose with a moderate nitrogen content (e.g., 12.6 % N) ensures satisfactory mechanical properties.

The granular material is metered into a rocket combustion chamber or into molds that are provided with liners. The vessel is vibrated and then evacuated to obtain a high bulk density. A mixture of nitroglycerine and inert plasticizers is then slowly pressed into the powder bed. The liquid fills the cavities in the powder bed and gelatinizes with the casting powder within several days at ca. 60 °C to form a compact body. The process is relatively sophisticated, but has main advantages: (1) propellant charges of any size and configuration can be manufactured, (2) charges consisting of combinations of propellants can be manufactured by using different casting powders.

Composite modified double-base propellants with a high solids content also contain a polymer binder that is compatible with the double-base matrix.

Slurry Casting Process. The slurry casting process is an alternative to the two-stage casting process. A pourable slurry is prepared using small spherical gelatinized nitrocellulose particles (fluid ball) and plasticizers.

The thixotropic fluid ball is stirred with a mixture of nitroglycerine and inert plasticizers in planetary stirrers in vacuo, other additives follow. The slurry is then poured under vibration and reduced pressure into casting molds and hardened for several days at 50 – 70 °C to form compact bodies. The components used in this process for producing nitrocellulose plastisol propellants have been widely varied. For example, other energetic plasticizers have been used instead of nitroglycerin, such as pentaerythritol trinitrate (PETriN). As with the casting process, oxygen- containing salts, aluminum powder, and nitramines can be incorporated into the slurry. Cross-linked polymers can also be added. Instead of fluid balls, poly(vinyl nitrate) or poly(vinyl chloride) granules have also been used. By using cross-linked polymers and crystalline fillers, the slurry casting process and its products form the transition to composite propellants produced by analogous processes [16], [88].

6.2. Composite Propellants

Casting Process. The manufacture of most rocket propellant charges based on composite

propellants follows the same process, namely by mixing the components into a viscous liquid which is then poured into molds and cured at elevated temperatures. Composite propellants consist of a polymeric binder and a powdery filler (Section 3.1.2). The binder serves both as a fuel and as a matrix for accommodating the filler; the latter contains chemically bound oxygen for combustion (e.g., ammonium or potassium perchlorate, ammonium nitrate). Typical explosives such as HMX, RDX or NQ and TAGN may also be used. Metal powder (e.g., aluminum powder) is sometimes added to increase the combustion temperature and avoid instability during burning [11], [16], [89], [90].

Pretreatment. Although a large number of cross-linked polymers have been tested, hydroxyl-terminated polybutadienes (HTPB) are now mainly used for the casting process. The liquid prepolymer is carefully dried (moisture content $< 0.1\,\%$) because water can react with the cross-linking agents or adversely affect the wetting of the fillers. The prepolymers are subjected to strict quality control, particularly as regards their proportion of reactive groups, to obtain optimum mechanical properties.

The concentration and grain size distribution of the filler influence the viscosity and thus the processing of the casting materials, as well as the mechanical properties and burning behavior of the propellant. The fillers therefore have defined grain size distributions. Compositions containing two or three different grain sizes are used to obtain good casting properties in the sense of a high packing density. The oxygen- containing salts are carefully dried and then ground to the desired size in mechanical mills or fluid-energy pulverizers (grain size $< 5\,\mu m$). An anticaking agent is often added to prevent agglomeration of the finely ground material which should be processed within a few hours. Friction-sensitive fillers such as explosives are ground in the presence of water in an apparatus equipped with high-speed rotors, or are produced by crystallization.

Mixing. The binder prepolymer is first mixed with the inert additives (metal powder, burning modifiers, wetting agents, etc.) and, if necessary, with inert or explosive plasticizers. Modern mixers have vertically operating planetary kneader blades and are equipped with a vacuum device. The mixer has a double jacket for heating the materials to ca. 40 – 60 °C. After the binder and additives have been thoroughly mixed, the oxygen-containing salts and explosives are added. The mixture is kneaded under vacuum for several hours to ensure good wetting and degassing. After adding and mixing the curing agents are added.

Casting. The homogenized casting material is fed into the pouring device by an outlet at the bottom of the mixer or by tipping it. Highly viscous materials can be forced out by means of a plunger. The pretreated and evacuable casting molds often have a perforated plate at the filling end to ensure uniform filling. In many cases the materials are poured directly into the rocket chambers which contain a profiled core in the case of an internal burner. With highly viscous materials this core may be also pressed into the propellant after pouring. The casting device and the molds can be made to vibrate to improve the flow. The formulation of the propellant must be adjusted so as to ensure a sufficiently long pot-life. This is especially important with large propellant charges where casting can take several hours. The rocket chambers or casting molds are placed in heated chambers where they were cured for several days at ca. 60 °C. Rapid curing at relatively high temperatures should be avoided to prevent internal stresses, which are especially important with charges of large diameters. The casting devices are then allowed to cool, and any cores are removed.

Propellant charges of any size can, in principle, be manufactured by the casting process. The production of charges with small diameters is, however, only economical if extrusion is more expensive or more hazardous. The upper limit is governed by the capacity of the mixer and permitted safety distance. Several time-phased mixers are used for very large propellant charges.

Attempts have been made to employ continuously operating mixing and kneading machines, such as extruders, to avoid mixing of large amounts of propellant. Since the residence time in extruders is limited, the mixing and kneading time is often insufficient to produce an optimum propellant in the case of highly filled composite propellants. To overcome this problem equipment has been developed in which several individually controlled continuously fed, mixing chambers are connected in series. The

casting material can be removed continuously via an extruder outlet [91].

Extrusion Process. An extrusion process has to be employed for propellants with thermoplastic binders or propellant mixtures with a viscosity that is too high for casting. The pretreatment of the components and the mixing of the propellant materials are carried out as described before [92]. The highly viscous materials are kneaded in extruders and then forced through suitable dies into molds or combustion chambers. The processing temperatures (80 – 120 °C) are considerably higher than in the casting process. Horizontal mixers have also been used, which have an outlet screw in the bottom of the trough.

The development of insensitive gun propellants (LOVA) has led to products with chemical compositions comparable to those of composite propellants. They consist of a thermoplastic binder or a cross-linked polymer, explosive and nonexplosive plasticizers, and nitramines (e.g., RDX, HMX, NQ, or NTO). Also gun propellants of the composite type with thermoplastic binders are extruded, after conventional mixing and kneading, from extruders through dies. Propellants containing cross-linked polymers have to be after-cured at elevated temperatures (60 °C). For a continuous process double-screw extruders are used.

6.3. Special Propellant Devices

Caseless Ammunition. The first generation of caseless ammunition consisted of powder or granules that were compressed into mechanically stable grains with the aid of solvents or adhesives. The projectile and the consumable ignition device were embedded in the grain. Although the grains were provided with a protective coating they sometimes ignited unintentionally in previously fired guns (cook off). Com-

posite propellants containing energetic materials with a high thermal stability are used to overcome these problems. Finely crystalline HMX is homogenized with an inert binder and the mass formed into a porous grain. The porosity is chosen such that the specimen reacts within the required time. Polynitrophenylene is employed as an energetic material for caseless ammunition for the G11 rifle by Dynamit Nobel (Fig. 4) [64], [65], [93].

Combustible Cases. The production of combustible cases from matted cellulose fibers was developed in the United States. Figure 7 shows a modification of this process for the manufacture of 120-mm ammunition (Fig. 8) [94]. Cases for modular propellant charges are produced similarly [95].

Figure 8. Combustible case for 120-mm ammunition of the Leopard 2 armed tank (Rheinmetall)
The projectile is subsequently inserted at the front of the case (right-hand side). The shaped part at the back (left-hand side) accomodates the steel base.

A pulp consisting of cellulose fibers and other raw materials in a water bath are deposited on a mold by sucking off the water. The fibers are distributed uniformly in all directions, resulting in matting. The case already has some mechanical stability, its shape is determined by the geometry of the mold. The final shape is obtained by pressing and machining. After pressing, the cases may be immersed in an impregnation bath to give the required mechanical stability. This step is not necessary if special impregnating additives are included in the pulp (Figs. 7, 8).

7. Test Methods

The properties of propellants must be studied in research and during their development, production, and use. Tests are used to determine safety of handling (permission for transport), chemical stability and compatibility, mechanical and physical properties, and internal ballistic properties. These tests can be supplemented by other methods to measure process parameters and sensitivity toward external influences.

Many test methods have been standardized at a national or international level. Test methods for the *military sector* are specified in

France	Manuel des modes operatives
Germany	Technische Lieferbedingungen (TL)
NATO	Standardisation Agreement (STANAG)
United Kingdom	Defence Standard (DEFSTAN)
United States	Military Standard (MIL-Std.)

The following organizations are responsible for the *civilian sector*:

France	Centre d'Etudes et Recherches de Charbonnages de France (CERCHFR)
Germany	Bundesanstalt für Materialforschung (BAM)
Japan	Japanese Industrial Standards
United States	National Bureau of Standards
UNO	United Nations Committee of Experts on the Transport of Dangerous Goods

Tests for safe handling and chemical and physical properties are the same as those used for explosives (→ Explosives, Chap. 8.). Other special internal ballistic tests must, however, also be carried out.

Burning Behavior (Ballistic Bomb). The burning behavior of a propellant powder is investigated with a pressure proof (≤ 1 MPa) screw-lid vessel made of steel and fitted with a piezoelectric pressure recorder. The pressure in the *ballistic bomb* is determined as a function of time. Alternatively, the rate of pressure increase is measured as a function of pressure. These parameters, especially the dynamic vivacity of a powder, are used for the preliminary design of a powder charge. If the form function is known, the linear burning rate of the powder can be calculated [96].

Gas pressure (crusher) gages similar to those used in weapons are used to measure the pressure curve of gun propellant charge. In the gage, however, the gun barrel is replaced by a rupture diaphragm.

Burning Rate. The linear burning rate of solid rocket propellants is measured in a pressure vessel known as a *Crawford Bomb* . Propellant rods (diameter 4 – 5 mm) are burned at a specified pressure (2 – 25 kPa). The completely insulated rods are ignited at one end and burn perpendicular to the burning surface. The burning rate is measured with wire detectors. The pressure is kept virtually constant by means of an equalization vessel. Similarly constructed bombs are used to determine the linear burning rate of gun propellant charges ($\leq$ ca. 600 kPa) [97].

Standardized combustion chambers of widely differing design are employed to determine the burning behavior of rocket propellant charges.

Heat of Explosion. The heat of explosion of a propellant powder (loading density generally 0.1 g/cm^3) can be calculated from the difference between the energies of formation of the powder constituents and the combustion products. Unlike the heat of combustion, the experimentally determined heat of explosion depends on the loading density. The calorific value is usually related to liquid water [96].

8. Safety Precautions and Environmental Protection

The production, handling, and transport of propellants are governed by national laws and regulations and international recommendations [58]. Safety measures are based on the classification of the energetic material as a dangerous substance. Regulations for the construction of storage and production facilities, quantitative limits, safety areas etc. are designed to minimize the effects on the environment in the case of an incident. The environmental effects caused by the production, use, and disposal of propellants depend on their chemical composition. In the case of liquid propellants, hydrazine, its derivatives, and fluorine- or chlorine- containing oxidizers are especially dangerous as potential pollutants. The following components of solid propellants must be classified as environmental pollutants: perchlorates, heavy-metal salts, and aromatic compounds (stabilizers).

Environmentally hazardous products, such as nitrogen oxides and hydrogen chloride, can be formed when propellants are burnt. Less nitrogen oxides are formed when combustion takes place at high pressure. The large quantities of hydrogen chloride that are produced during the start of a space rocket are especially hazardous for the environment if these are released at high altitude.

The environmentally safe disposal of propellants associated with the demilitarization of munition and abandoned polluted areas (e.g., ammunition factories, training areas, airports) presents a serious task for relevant experts.

As in the case of civilian products, material recycling is preferable to chemical, biological, or thermal treatment [98]. Biological methods will become increasingly important for treating contaminated soil.

The toxicological effects of propellant components and processing aids are described in national dangerous goods regulations.

1. Introduction

Propene, $CH_3-CH{=}CH_2$, M_r 42.081, [*115-07-1*] was the first petrochemical raw material to be employed on an industrial scale and was used more than 60 years ago in the production of isopropanol. For a long time, propene was to some extent overshadowed by its olefin homologue ethylene. However, part of propene's turbulent development and expansion since 1965 is also due to the success of ethylene: Being a byproduct of ethylene production, many important areas of application were opened up to propene by the chemical industry. Secondary products of propene, such as polypropylene, acrylonitrile, propylene oxide, and in Europe cumene, have now clearly overtaken the classic secondary product isopropanol in importance.

2. Physical Properties

Important physical properties are as follows:

mp	− 185.25 °C
bp	− 47.70 °C
t_{crit}	91.76 °C
p_{crit}	4.621 MPa
ϱ_{crit}	0.22 g/cm^3
Molar volume	21.976 L (STP)
Gas density	1.9149 g/L (STP)
Density relative to air	1.49
Heat of fusion	71.37 kJ/kg
Lower heating value	45 813 kJ/kg
Enthalpy of formation ΔH_{298}	20.43 kJ/mol
Entropy S_{298}	0.227 kJ mol^{-1} K^{-1}
Free energy of formation ΔG_{298}	62.65 kJ/mol
Explosion limits in air (at 1 bar and 20 °C)	
Lower	2.0 vol % (35 g/m^3)
Upper	11.1 vol % (200 g/m^3)
Ignition temperature	455 °C

The temperature dependence of typical properties is given in Table 1.

3. Chemical Properties

The chemical properties of propene are, like those of ethylene, characterized by the reactivity

of its double bond. Propene undergoes a number of industrially important polymerization, addition, and oxidation reactions (see Chap. 6).

4. Production

Although propene is one of the most important feedstocks for the organic chemicals industry, it is produced almost entirely as a byproduct because it is obtained in sufficient amounts in ethylene production by steam cracking and in some refinery processes (primarily cat cracking).

Whereas in Europe, *refineries* satisfy on average only 20 % of the chemical industry's consumption of propene [5], in the United States they meet more than 40 % of the consumption demand [6], [7]. Despite this high figure, refineries in the United States consume ca. 75 % of their propene production in in-house, nonchemical applications [8]. This propene excess is utilized in gasoline production (alkylate and polymer gasoline; see Section 6.2), (→ Oil Refining, Chap. 3.7.), to produce liquefied petroleum gas (LPG, → Liquefied Petroleum Gas), and as heating gas.

A trend toward less severe cracking conditions and thus to increased propene production has been observed in *steam cracker plants* using liquid feedstock that have been designed since the mid-1980s. The increased consumption of propene has also boosted the demand for processes for propene production by *catalytic dehydrogenation* of propane. Various processes suitable for this purpose have been developed and in some cases tested.

4.1. Production as Byproduct of Ethylene Production

The influences of cracking feedstocks and cracking conditions on the composition of the cracked gas are described in detail in Ethylene (→ Ethylene, Chap. 5.1.).

A sour-gas-free, anhydrous C_3 fraction is obtained as overhead product from the depropanizer (a) in the processing of cracked gas. This fraction contains the C_3 hydrocarbons of the cracked gas (i.e., propane, propene, propadiene, and propyne) as well as traces of C_2 and C_4 hydrocarbons. Because of its propadiene and propyne content (depending on the cracking conditions, these can total up to 8 mol %), this C_3 fraction does not meet product specifications and therefore requires further treatment.

Figure 1 shows a typical flow diagram for the further processing of the C_3 fraction in a steam cracker plant. The C_3 fraction is fed to a selective hydrogenation unit (b) to remove propadiene and propyne. This hydrogenation can be performed in the gas and liquid phases (pressure ca. 18 bar), palladium catalysts being used in both. The amount of hydrogen added is calculated so that, on the one hand, complete conversion of C_3H_4 to C_3H_6 is achieved, and on the other, the smallest possible amount of propene is hydrogenated to propane. In practice a molar $H_2 : C_3H_4$ ratio of ca. 1.5 has proved suitable.

The reaction conditions of C_3 hydrogenation in the gas phase differ from those in the liquid phase. In gas-phase hydrogenation the reaction is controlled by means of the operating temperature, which may be between 50 and 120 °C, depending on the preparation and aging state of the catalyst. With liquid-phase hydrogenation the reaction is controlled by the hydrogen partial pressure. The operating temperature of 15 – 25 °C is considerably lower in this case. Adiabatic fixed-bed reactors with intermediate coolers, as well as isothermal tubular reactors, have proved suitable for the exothermic hydrogenation reaction in both phases.

Characteristic of a hydrogenation with metered addition of hydrogen is the formation of smaller amounts of oligomers (mainly dimers and trimers). If required by the propene product specification these can be scrubbed out following hydrogenation with a small amount of C_3 in scrubber (c). The mixture of oligomers and scrubbing agent is recycled to the depropanizer for C_3 recovery, and the oligomers are subsequently led into the pyrolysis gasoline fraction.

The methane introduced with the hydrogen (in liquid-phase hydrogenations, the unconsumed hydrogen as well) is then stripped off (d) and recycled to the cracked gas processing unit of the steam cracker to recover entrained propene. The bottom product of the C_3 stripper meets the product specification of *chemical-grade propene.*

Chemical-grade propene is purified to polymer-grade propene in a downstream

propene – propane separation column (e). A single water- cooled column designed for this purpose is illustrated in Figure 1. Such a process is only one of several variants that are discussed in more detail in Section 4.1.1. At this point, reference may be made only to one advantage, which provides for the (not essential) integration of propene – propane separation in the steam cracker plant. In modern plants the cracked gases are usually cooled to ambient temperature in a water scrubbing tower after the oil fractionation. The circulating water is heated to 80 to 85 °C in this operation and must be cooled again to be reused in the water scrubbing tower. The heated circulating water can therefore be used to heat the propene – propane separation stage and thus save energy. Also, other heat consumers (e.g., the reboiler of the C_3 stripper) may be supplied economically from this energy source. The propane separated in the C_3 splitter is usually (like ethane) recycled as cracking feedstock.

4.1.1. Variants of Propene – Propane Separation

The closely similar boiling curves of propene and propane (*bp* of propane −42.1 °C) require highly complex separation units. The internal reflux ratio is generally between 0.90 and 0.97 (depending on the feedstock composition, product purities, column pressure, and number of trays). For this reason the propene – propane separation is a process unit in which the development of energy-saving solutions is worthwhile.

Single-Column Process. In principle, separation can be carried out in a single column (generally containing 150 – 200 trays), as illustrated in Figure 1 (e). The reflux can be condensed with cooling water (column pressure 16 – 19 bar) or in air coolers (column pressure 21 – 26 bar). However, for the throughputs that are common nowadays, huge column diameters are required, and transportation of these huge units (or parts of them) by rail or road is difficult. Thus the double-column process has been developed where the separation is carried out in two parallel columns that are smaller in diameter and can therefore be transported more easily. This double- column process requires only ca. 55 % of the original amount of cooling water.

Double-Column Process. The double-column process is illustrated in Figure 2. In this process, only the reflux from the second

separation column (b) is condensed with cooling water. The pressure of the first column (a) is so high (ca. 25 bar) that its overhead vapors (ca. 59 °C) can be liquefied in the reboiler of the second column (ca. 18 bar, 51 °C) and serve as heat medium. Each column produces ca. 50 % of the propene product. The bottom product from the first column is the feedstock for the second column. Heating the first column with warm water is still possible with this process.

Figure 2. Propene – propane separation by the double-column process
a) High-pressure C_3 splitter (ca. 25 bar); b) Low-pressure C_3 splitter (ca. 18 bar)

Heat Pump Process. If no cost-free (or even cost-saving) heating medium such as the warm circulating water of the steam cracker is available, then separation according to the heat pump process is possible (see Fig. 3). In this process the higher propene – propane ratio in the gas phase at lower pressure is utilized. The overhead vapors of the C_3 splitter (a), which operates at ca. 10 bar, are heated slightly in the reflux subcooler (b) and then compressed to a pressure that enables them to be liquefied in the reboiler (e). Apart from the energy needed to drive the compressor (c), only a small amount of cooling water is required in the aftercooler (d).

Figure 3. Propene – propane separation by the heat pump process
a) C_3 splitter; b) Reflux subcooler; c) Compressor; d) Postcooler; e) Condenser and reboiler

Lower Product Quality. Energy savings in the propene – propane separation can be achieved not only by appropriate process design, but also by restricting the purity of the polymer-grade propene to the absolute minimum necessary. Figure 4 shows the relative complexity of separation required for higher purities, relative to a minimum propene purity of 99.0 mol %. The complexity of separation and thus the energy consumption increases considerably with propene purity, and even more sharply as the number of column trays decreases.

4.1.2. Apparatus and Construction Materials

In steam cracker plants, work-up of the C_3 fraction occurs above 0 °C and below 100 °C (with the exception of gas-phase hydrogenation, where the temperature can rise to ca. 200 °C). The C_3-treatment section of the plant thus does not place any special requirements on materials. Normal carbon steels and fine-grained steels (such as WSt 36) are used; aluminum is employed for special heat exchangers (such as propene-heated reboilers of propene – propane splitters).

In general, turbocompressors are used as compressors for the *heat pump variant* of the propene – propane separation. Their power requirements for a propene capacity of 100 000 t/a and a product purity of 99.5 mol % are 1400 – 1500 kW. The compressors are driven by electric motors or steam turbines, which can be integrated into the steam system of the steam cracker.

Highly chargeable sieve trays spaced relatively close together are incorporated in the generally 70 – 90-m-high C_3 splitters. The apparatus used in steam cracker plants is discussed in more detail in → Ethylene, Chap. 5.3.2.

Figure 4. Relative complexity of the propene – propane separation as a function of enhanced propene purity (relative to a minimum propene purity of 99 mol %)
Base: Feedstock containing 93 mol % propene, 7 mol % propane; bottom product containing 30 mol % propene, 70 mol % propane
—- single column with 200 trays
– – – single column with 150 trays
a) Separation at 10 bar (heat pump process); b, d) Separation at 18 bar (reflux condensation with cooling water); c) Separation at 25 bar (reflux condensation with air cooler)

4.2. Production as Byproduct of Refinery Processes

The propene produced in refineries also originates from cracking processes. However, these processes can be compared to only a limited extent with the steam cracker for ethylene production because they use completely different feedstocks and have different production objectives.

Refinery cracking processes operate either purely thermally or thermally – catalytically. By far the most important process for propene production is the *fluid-catalytic cracking* (FCC) process in which the powdery catalyst flows as a fluidized bed through the reaction and regeneration phases (→ Oil Refining, Chap. 3.2.). This process converts heavy gas oil preferentially into gasoline and light gas oil.

Purely thermal cracking processes, which in refineries contribute to propene production, are employed in coking and visbreaker units (→ Oil Refining, Chap. 3.6.4.1., → Petroleum Coke, Chap. 3.). In *coking units* (*delayed coking* and *fluid coking*), residues from the atmospheric and vacuum distillation of the crude oil undergo relatively severe cracking and are thereby converted into gas oil, coke, gasoline, and smaller amounts of cracked gas (6 – 12 wt % of C_4 and lighter). The cracked gas from the coking unit normally contains 10 – 15 mol % C_3, mostly propane. In *visbreaker units*, vacuum residues are subjected to mild cracking, with the object of reducing the viscosity of the residue oil. Smaller amounts of gas oil, gasoline, and cracked gas (2 – 3 wt % of C_4 and lighter) are formed here.

The working-up of refinery gases to isolate the C_3 fraction generally occurs as follows: first, the light components are separated at ca. 15 bar in a deethanizer, whose upper part is operated as an absorber with gasoline and oil as scrubbing agents. The C_5 and heavier hydrocarbons are removed from the bottom product in a connected debutanizer. The C_3–C_4 fraction obtained as overhead product is normally desulfurized on molecular sieves and dried, before being split into individual fractions in a final depropanizer.

4.3. Propane Dehydrogenation

The principal sources of propene are the steam cracking of hydrocarbon feedstocks (Section 4.1) and refinery conversion processes [e.g., fluid catalytic cracking, visbreaking, and coking (Section 4.2)]. Despite the magnitude of the sources, in these cases propene is a byproduct of processes for the manufacture of other products, such as ethylene in the case of steam cracking and motor gasoline in the case of catalytic cracking. The availability of propene is

determined primarily by the demand for the main products, although factors such as feedstock and operating conditions have a significant influence on propene yield. The increasing demand for propene derivatives throughout the 1980s, especially for polypropylene, outstripped the availability from these established sources, and processes for the "on-purpose" production of propene by the dehydrogenation of propane from natural LPG fields have been developed commercially.

Propane dehydrogenation is an endothermic equilibrium reaction that is generally carried out in the presence of a noble- or heavy-metal catalyst such as platinum or chromium.

$$C_3H_8 \longrightarrow C_3H_6 + H_2$$

The process is highly selective; overall yields of propene from propane of ca. 90 % are claimed for commercially available processes. Higher temperature and lower pressure increase propene yield. However, increased process temperature also causes pyrolysis (cracking) of propane to coke in addition to its dehydrogenation to propene (i.e., reduced selectivity), whereas lower operating pressure increases selectivity. Coke formation wastes feedstock and deactivates the dehydrogenation catalyst. Consequently, propane dehydrogenation processes are operated near atmospheric pressure at around 500 – 700 °C.

A number of technologies are available commercially for the dehydrogenation of propane to propene: these include *Oleflex* developed by UOP, Des Plaines, Illinois, United States; *Catofin* developed by Air Products and Chemicals, Allentown, Pennsylvania, United States; and *STAR* developed by Phillips Petroleum, Bartlesville, Oklahoma, United States. These processes differ in their modes of operation, the dehydrogenation catalyst, and the methods of catalyst regeneration.

4.3.1. Oleflex Process

The Oleflex process was developed from the *Pacol* process (UOP), which is used to dehydrogenate $C_{10} - C_{14}$ paraffins to olefin feedstocks for the production of intermediates for synthetic detergents [9] (→ Hydrocarbons). The Oleflex process is an adiabatic process in which the heat of reaction is supplied by reheating the process stream between the different reaction stages. The process is operated at a slight positive pressure, and a proprietary platinum catalyst is used. Fresh propane feed is mixed with recycled hydrogen and unconverted propane and admitted to a train of three radial-flow moving-bed catalytic reaction vessels (Fig. 5). The process is continuous, and overall selectivities for propene of 89 – 91 % are claimed. The dehydrogenation catalyst circulates through the reactor section before passing to a separate regeneration vessel where coke is removed from the surface of the catalyst by combustion in air (UOP Continuous Catalyst Regeneration technology). The regenerated catalyst is returned to the first of the dehydrogenation reactors. Propene is recovered by conventional deethanizer – depropanizer splitting (see Section 4.1). Advantages claimed by the Oleflex process include continuous operation; a uniform, time-invariant catalyst activity profile; and isolation of the oxidative catalyst regeneration phase from the dehydrogenation reactor [9].

4.3.2. Catofin Process

The Houdry (Air Products) Catofin process (see Fig. 6) operates under a slight vacuum at 550 – 750 °C [10]. The process utilizes adiabatic, fixed-bed multiple reactors. The dehydrogenation catalyst consists of activated alumina pellets impregnated with 18 – 20 wt % chromium. The process is cyclic and includes a reaction period, discharge of the reactor, and regeneration of the catalyst in situ. Multiple reactors are used in parallel to achieve continuous plant throughput, with the reactor containing the coked catalyst being taken off stream for the regeneration step. The mixed fresh and recycle propane stream is preheated to 600 – 700 °C and fed to the reactor at ca. 30 kPa (one-third atmospheric pressure): the influence of reactor pressure and temperature on propene yield is shown in Figure 7. Combustion of the deposited coke on the catalyst during regeneration heats the catalyst bed, and this energy is released to the endothermic dehydrogenation reaction when that reactor is returned to operation. The overall selectivity of propane to propene is reported to be about 87 % [10]. Propene is recovered by a con-

ventional propane –propene splitter. Advantages claimed for the Catofin process include extended catalyst life and utilization of the heat generated in the exothermic regeneration step to assist dehydrogenation.

4.3.3. Phillips STAR Process

The Phillips Steam Active Reforming (STAR) process for the dehydrogenation of paraffins ($\leq C_5$) [11] differs significantly from other dehydrogenation processes. Here, steam is used as a diluent to maintain an overall positive pressure in the process reactor and simultaneously reduce the partial pressure of the hydrocarbons and hydrogen present. Thus, the equilibrium is shifted toward increased conversion. In addition, the process is performed isothermally. The preheated feedstream containing steam is admitted to a chain of multiple fixed-bed reactors. Each reactor consists of multiple catalyst-packed tubes in a furnace firebox, which supplies heat to the catalyst. Reactor operation is cyclic (i.e., one reactor is taken offline sequentially for catalyst regeneration), whereas dehydrogenation is maintained continuously. Catalyst deactivation occurs due to coke deposition, and after about 7 h on-line, an off-line catalyst regeneration by combustion for ca. 1 h is required. The catalyst is completely recovered, and overall catalyst lifetimes of one to two years have been reported [11]. Advantages claimed for the STAR process include 80 % yield of propene on propane; isothermal operation that ensures sufficient heat input to promote dehydrogenation; and the steam diluent that reduces the hydrocarbon pressures while maintaining a more practical process pressure. Carbon dioxide (formed by side reactions) must be removed from the reactor product stream prior to propene separation.

4.3.4. Linde Process

The Linde process [12] operates at low reaction temperature and nearly isothermal condi-

tions which are designed to minimize thermal cracking and coke formation. The process uses a chromium oxide catalyst in a fixed-bed tubular reactor. The catalyst has a relatively long cycle time (9 h) before regeneration is necessary. The propane feedstream is not diluted with hydrogen or steam as in other processes, resulting in high selectivity (e.g., 91 %). The process is claimed to have low power requirements and low capital costs. Product separation yields polymer-grade propene.

– – – mole fraction of methyl acetylene

5. Storage, Transportation, Quality Requirements

There is an extensive propene pipeline network in Texas and Louisiana in the United States and a very limited system in Belgium in Western Europe. In other locations propene transportation is largely by road, rail, and ship. This discontinuous delivery and supplying of consumers requires large storage capacities on the part of both propene producers and propene consumers.

Liquid propene is normally *stored* at ambient temperature in spherical pressure tanks with diameters up to 20 m. Propene is however also stored virtually pressureless at −47 °C, particularly for very large amounts (→ Liquefied Petroleum Gas, Chap. 5.). The latter form of storage requires reliquefaction devices.

Propene is *transported* by road and rail in cylindrical pressurized tanks at ambient temperature. The standard railway tanker holds 42 t of propene. In the case of road transport the maximum permitted overall truck weight of ca. 40 t restricts the propene load to ca. 20 t (corresponding to 40 m^3). In transportation by ship, batteries of smaller pressurized tanks as well as large atmospheric tanks with reliquefaction devices are used.

Quality Requirements. The quality requirements placed on propene vary widely depending on its subsequent use. Corresponding to production in steam cracker plants, two qualities are basically employed namely, the less pure chemical-grade propene and the highly pure polymer-grade propene. Examples of specifications for these two product qualities are given in Table 2. Depending on different posttreatment processes (in the case of polymer-grade propene) or different intended main uses (in the case of chemical-grade propene) the permissible concentrations of impurities may vary within relatively wide limits.

6. Uses

Global propene production for chemical uses increased strongly through the 1980s [13], equivalent to a global average annual increase of 5 % (see Table 3).

The extent of steam cracker and refinery production of propene varies from region to region [13]. In the United States, refinery production has a much greater share of total availability than in other regions due to a large motor gasoline market that requires an adequate FCC capacity and a preponderance of ethane feedstock for steam crackers, resulting in lower yields of steam cracker propene. The proportion of propene produced by steam cracking between 1980 and 1990 is given in Table 4.

The three commercial grades of propene are used for different applications. *Refinery-grade* propene (i.e., 50 – 70 % pure propene in propane) is obtained from refinery processes. The main uses of refinery propene are in LPG for

thermal use or as an octane-enhancing component in motor gasoline. Refinery-grade propene can also be used in some chemical syntheses (e.g., of cumene or isopropanol).

Chemical-grade propene is used extensively for most chemical derivatives (e.g., oxo alcohols, acrylonitrile, or polypropylene).

*Polymer-grade*propene contains minimal levels of impurities such as carbonyl sulfide that can poison catalysts used in polypropylene and propylene oxide manufacture.

6.1. Thermal Uses

Propene has a calorific value of 45 813 kJ/kg, and refinery grade propene can be used as fuel if more valuable uses are unavailable locally (i.e., propane – propene splitting to chemical-grade purity). Refinery-grade propene can also be blended into LPG for commercial sale, provided no low limits exist on the olefin content of LPG (unsaturated hydrocarbons produce more smoke than saturated hydrocarbons and have a lower calorific value).

6.2. Motor Gasoline Uses

Propene is used as a motor gasoline component for octane enhancement, via dimerization – formation of polygasoline or alkylation.

6.2.1. Polygasoline Production-Dimerization

Polymerization of refinery-grade propene at high temperature and pressure with a catalyst such as phosphoric acid produces *polygasoline* containing dimers, trimers, and tetramers. Polygasoline is used as a blendstock in motor gasoline. In 1977, *dimerization* of propene to isohexenes at lower temperature and pressure by using nickel complex – alkylaluminum halide catalysts was developed by Institut Français de Petrole (Dimersol process) [14]. Propene conversions of $> 90\,\%$ are achieved. The product, *dimate*, has a low vapor pressure and a high blending octane rating (R + M)/2 of 89 (for a definition of blending octane rating, see → Octane Enhancers, Chap. 5.1.), compared to 86 for cat cracker gasoline and 87 for polygasoline.

6.2.2. Alkylation

Alkylation is an acid-catalyzed reaction between propene (or other light olefins) and isobutane to yield a highly branched higher alkane (2,3-dimethylpentane in the case of propene) of low vapor pressure and high octane rating [15]. The reaction catalyst is either hydrofluoric acid, which gives octane ratings of 90 – 92, or sulfuric acid, which gives octane ratings of 88 – 91 [16]. If *hydrofluoric acid* is used as catalyst a second reaction is promoted in which hydrogen is transferred from isobutane to propene to yield propane and isobutene. The latter then alkylates isobutane to produce trimethylpentanes in parallel with dimethylpentane from the direct alkylation. The choice of catalyst depends on feedstock and process conditions as well as octane rating.

6.3. Chemical Uses

The principal chemical uses of propene are in the manufacture of polypropylene, acrylonitrile, oxo alcohols, propylene oxide, butanal, cumene, and propene oligomers [13]. Polypropylene is the leading global consumer of propene (see Table 5). Other uses include acrylic acid derivatives and ethylene – propene rubbers.

Polypropylene (→ Polyolefins, Chap. 2.). Isotactic polypropylene is of great commercial importance. Polymerization of chemical-grade or polymer-grade propene is carried out by using Ziegler – Natta catalysts [17], in either a liquid-phase or a gas-phase process. Polypropylene has a high melting point, good rigidity, and good chemical and abrasion resistance. Weaknesses include poor thermal and UV stability, but these can be improved by appropriate stabilizers. Polypropylene is used widely, and global production exceeded 13×10^6 t in 1990.

Acrylonitrile. Acrylonitrile is obtained by catalytic oxidation of chemical-grade propene in the presence of ammonia (ammoxidation).

A number of commercial processes are available but the most significant is the Sohio process (→ Acrylonitrile) [18] in which a stoichiometric mixture of propene, ammonia, and oxygen is reacted over a catalyst at 400 – 500 °C. World consumption of acrylonitrile in 1990 was 3.7×10^6 t.

Propylene Oxide. Propene (polymer grade) can be converted into the ether propylene oxide either by hydrochlorination and epoxidation, or by reaction with an organic hydroperoxide [20], [21] (→ Propylene Oxide).

Propylene oxide is used as a raw material in the production of poly(propylene glycols), propanolamines, and polyether polyols, which themselves are intermediates for flexible and rigid polyurethane foams. Propylene oxide production in 1990 was 2.75×10^6 t, consuming some 2.2×10^6 t of propene.

2-Propanol. 2-Propanol is produced by the hydration of chemical-grade propene either in the presence of sulfuric acid or directly as a vapor-phase reaction in the presence of a catalyst at 180 – 270 °C [22]. Yields $> 70\,\%$ based on propene are achieved at high selectivity (e.g., $> 90\,\%$). 2-Propanol is used extensively as a solvent in paint, cosmetics, and pharmaceuticals. Global production of 2-propanol in 1990 was 1.4×10^6 t, representing 1.2×10^6 t of propene.

Table 5. Consumption of propene (in wt %)

Product	1980	1982	1984	1986	1988	1990	1995 *
Polypropylene	30	33	36	38	40	44	50
Acrylonitrile	19	18	18	17	15	14	12
Oxo alcohols	19	18	16	16	16	15	4
Propylene oxide	9	9	8	9	9	9	8
Cumene	10	9	9	8	8	8	7
Oligomers	8	7	6	5	5	4	3
Others	5	6	7	7	7	6	7

[19]

Cumene. Propene can be used to alkylate benzene to produce 1-methylethylbenzene (cumene) [23]. The reaction is usually undertaken with refinery-grade propene in the presence of phosphoric acid catalyst. Cumene is then oxidized to cumene hydroperoxide, which decomposes to phenol and acetone (→ Phenol, Chap. 4.1.). Global production of cumene was 2.3×10^6 t in 1990, representing 0.9×10^6 t of propene.

Oligomers. Propene oligomers are liquid polymers of propene with a low degree of polymerization. They are intermediates between polygasoline and the high polymer polypropylenes, and contain ten or more carbon atoms per molecule. Propene oligomers are prepared by acid-catalyzed polymerization. Depending on the degree of polymerization the products are used as lube oil additives or as detergent intermediates.

Hydroformylation. Propene reacts with carbon monoxide and hydrogen (synthesis gas) at elevated temperature and pressure in the presence of a transition-metal catalyst (e.g., a rhodium carbonyl catalyst) to give butanals (oxo process) [24]. *n*-Butanal is converted into the aldol and hydrogenated to produce 2-ethylhexanol.

Allylics. Propene can undergo many reactions to produce allylic compounds. In these reactions a methyl hydrogen atom is substituted and the carbon–carbon double bond is preserved (see ammoxidation page 12). The more important allylic derivatives include allyl chloride (3-chloropropene) [25] and acrolein (allyl aldehyde) [22]. Propene can be reacted with *acetic acid* in an acidic medium to produce allyl acetate (i.e., the double bond is retained in the molecule), or acetic acid is added to the carbon–carbon double bond to yield isopropyl acetate.

7. Economic Aspects

Propene is a byproduct of the production of ethylene by steam cracking (Section 4.1) or the production of motor gasoline by catalytic cracking (Section 4.2), so no direct manufacturing costs are attributed to these sources. Propene demand exceeds that from steam cracker sources, and marginal supplies are taken from refinery sources. *Propene economics* are based on its value in marginal applications: generally dimerization (Section 6.2.1) or alkylation (Section 6.2.2) for gasoline. The motor gasoline valuation of propene is set by the octane enhancement of motor gasoline by alkylate or Dimersol, both obtained from refinery-grade propene. Generally, motor gasoline absorbs incremental propene supplies, and all other uses must pay the equivalent octane value plus the costs of distilling refinery grade to the purity required. When propene demand in motor gasoline is weak, surplus refinery propene is returned to LPG uses or to refinery fuel (Section 6.1). When demand for propene is very high the value of the marginal supply rises above the octane value to reflect the new marginal use (e.g., in polypropylene).

Propene from the *dehydrogenation of propane* does have a direct manufacturing cost structure based on feedstock, utility, plant fixed costs, etc. In an environment in which propene demand exceeds the supply from steam crackers and catalytic crackers, propene values should cycle between a minimum of the cash cost of propane dehydrogenation and either a level necessary to justify the investment in further dehydrogenation plants or a higher level set by the demand for derivatives.

1. Introduction

Propionic acid [*79-09-4*], CH_3CH_2COOH, M_r 74.08, was first described by J. Gottlieb in 1844. In 1848 J. J. Dumas recognized that it belonged to the group of compounds known as fatty acids. Since it is the first fatty acid which can be salted out of aqueous solution, it was named propionic acid ($\pi\varrho\omega\tau o\sigma$ = first, $\pi\acute{\imath}\omega\nu$ = fat).

Propionic acid occurs naturally, predominantly in the form of its esters in some essential oils. It is also formed as the free acid in various enzymatic and fermentation processes, and is produced as a result of anaerobic carbohydrate fermentation in the stomachs of ruminants. Propionic acid derivatives are also important intermediates in various physiological cycles.

Industrially, propionic acid is used in the production of cellulose esters, plastic dispersions, and herbicides. It is also used to a limited extent in pharmaceuticals and in flavors and fragrances. Propionic acid is gaining increasing importance for the preservation of forage cereals and animal feeds because many putrefying and mold-forming microorganisms cannot survive in its presence. This fungicidal and bactericidal action is exploited to protect bakery products and cheese from attack by bacteria and mold.

Propionic acid is produced specifically by carbonylation of ethylene and oxidation of propionaldehyde; in addition, it is obtained in large quantities as a byproduct in the oxidation of hydrocarbons.

2. Physical Properties

Propionic acid, *mp* −20.8 °C, *bp* 141.3 °C (at 101.3 kPa) is a clear, colorless liquid with a

slightly pungent odor (odor threshold in air 0.03 vol %). Solid propionic acid forms monoclinic crystals and undergoes an increase in volume on melting of 12.2 % [1]. In the liquid state and in the gas phase a considerable portion of the molecules of propionic acid are dimerized as is the case with its lighter homologues acetic [*64-19-7*] and formic [*64-18-6*] acids [2–5]. Propionic acid is miscible with water and most organic solvents in all proportions. Propionic acid – water mixtures show a positive deviation from Raoult's law [3]. The heats of mixing of various binary and ternary mixtures of propionic acid are given in [6], [7].

Propionic acid forms azeotropic mixtures with many liquids [8–11], for example with water at 82.3 wt % water [*bp* (101.3 kPa) 99.98 °C]. The liquid – vapor equilibria of the system propionic acid – water at various pressures have been investigated [12]. Further data on the liquid – vapor system propionic acid – water and also on other binary mixtures of propionic acid are given in [13]. The solubility of propionic acid in ternary mixtures is described in [14], [15].

The temperature-dependence of the vapor pressure of pure propionic acid is shown in Table 1 and that of the density of the pure acid in Table 2. Table 3 shows the effect of temperature on the dynamic viscosity.

Table 3. Dynamic viscosity of pure propionic acid as a function of temperature [16]

t, °C	η, mPa · s
0	154.1
20	109.4
50	73.8
100	45.0
150	31.0

Other physical data are as follows:

Refractive index n_D^{20}	1.3865 [18]
Surface tension toward air	
(at 20 °C)	26.7×10^{-3} N/m [19]
(at 90 °C)	19.7×10^{-3} N/m

The specific heat of aqueous propionic acid solutions has been measured by ACKERMANN [28]. The values increase with increasing temperature, but decrease with increasing propionic acid concentration.

A graphical presentation of the temperature dependence of vapor pressure, heat of vaporization, specific heat, density, viscosity, surface tension, and thermal conductivity of gaseous and liquid propionic acid is given in [29].

3. Chemical Properties

As the third member of the homologous series of aliphatic monocarboxylic acids, propionic acid is still quite reactive and undergoes all reactions typical of these acids. It readily forms salts, amides, acid halides, and an anhydride (see Chap. 11). Esters are formed with alcohols and olefins, and with acetylenes the corresponding vinyl esters (→ Vinyl Esters).

The reactions of propionic acid differ from those of acetic acid because of the inductive effect of the methylene group. Thus, propionic acid is attacked by alkaline permanganate solution more readily than acetic acid, whereby it is degraded nonselectively into carbon dioxide, oxalic acid, and lactic acid [30].

Ionic substitution reactions also preferably occur at the methylene group. Chlorination in the presence of halogen-transfer reagents (e.g., PCl_3) gives α-chloropropionic acid. Radical chlorination (presence of peroxides, UV radiation) yields β-chloropropionic acid [31], [32]. Both acids are important intermediates in the production of herbicides and pharmaceuticals (see Section 11.4).

Thermal decomposition of calcium propionate or passage of propionic acid vapor over metal oxides at 300 – 400 °C gives diethyl ketone, which is used in fairly large quantities as an industrial solvent.

4. Production

Industrially, propionic acid is currently produced almost exclusively by three different processes:

1) Carbonylation of ethylene with carbon monoxide and water
2) Oxidation of propanal
3) Direct oxidation of hydrocarbons

Processes such as production of propionic acid as a byproduct in the synthesis of hydroxylammonium salts from 1-nitropropane [*108-03-2*] [33] (→ Hydroxylamine, Chap. 4.4.), by wood distillation, or by nitric acid oxidation of 1-propanol [*62309-51-7*] have become obsolete, although the latter gives propionic acid in 90 % yield [34]. Synthesis of propionic acid via the alkali melt of an *n*- and isopropanol mixture could never compete successfully with other processes, although propionic acid was obtained with > 98 % yield [35], [36]. The carbonylation of ethanol [*64-17-5*] [37] and acetic acid [*64-19-7*] [38] have also not yet been carried out industrially.

The *Koch synthesis* has been investigated intensively [39], [40]. As a carbonylation reaction of ethylene [*74-85-1*] in a strongly acidic medium, it is a variant of the Reppe synthesis. However, compared with the latter it never achieved much industrial significance and was carried out with little success.

Other possible sources of propionic acid, which are not used industrially for economic reasons, are its formation as a byproduct in the high- and low-pressure carbonylation of methanol [*67-56-1*] to give acetic acid (2 % formation of propionic acid), the atmospheric oxidation of

n-butene [*25167-67-3*] (4 % formation of propionic acid), and the direct reaction of ethylene, carbon monoxide, and water over noble-metal catalysts [41–49].

Processes for making propionic acid accessible specifically by C_1-*chemistry* have yet to be assessed for their future importance. Two-step reactions have been described, in which propionic acid is obtained directly from synthesis gas (20 – 60 bar, 150 – 160 °C, Rh catalysts) [50], [51]. With the current availability of ethylene and naphtha these processes are, however, not yet competitive.

It is sometimes desirable, to use propionic acid produced by *natural methods*, particularly for the use of propionic acid in flavors and fragrances. Appropriate microbiological and enzymatic processes have been developed, which are usually based on the anaerobic fermentation of starch or sugars [52–54]. However, the expensive production of this "natural" propionic acid limits its use to special areas of application.

4.1. Carbonylation of Ethylene (BASF Process)

In the Reppe synthesis (see → Carbonylation, Chap. 4.1.) ethylene is reacted with carbon monoxide [*630-08-0*] and water in the presence of $Ni(CO)_4$ [*13463-39-3*] according to the following equation:

$$CH_2 = CH_2 + CO + H_2O \xrightarrow{Ni(CO)_4} CH_3CH_2COOH \qquad \Delta H = -164.5\ \text{kJ/mol}$$

The reaction takes place at high pressure and is characterized by low raw material costs, high conversion, high yield, and a simple workup.

Process Description (Fig. 1) [25]. Ethylene and carbon monoxide are compressed and continuously pumped into the high-pressure reactor (a) together with feed solution. The crude propionic acid formed at 100 – 300 bar and 250 – 320 °C is drawn off at the head of the reactor and cooled in a heat exchanger (b) with production of steam. Part of the cooled reaction product is recycled to the reactor for temperature regulation (c), the main quantity is allowed to expand and is separated into an off-gas and a crude acid stream (d). Nickel is recovered from the off-gas and led back into the reactor. The off-gas is incinerated with recovery of heat. The crude acid stream is subsequently dehydrated and worked up by distillation in several columns (e). The nickel salts thus formed are recycled into the process. The pure propionic acid is finally obtained by distillation. The product residue is channeled out of the process.

Variants of the Reppe and Koch syntheses are described in [40], the effect of inorganic salts on the reaction conditions and yield is discussed. Boric acid is reported to accelerate the reaction and hinder the precipitation of catalyst salts [55].

4.2. Oxidation of Propanal

The oxidation of propanal [*123-38-6*] is an important route to propionic acid. This route is economically attractive although two steps (production of propanal and subsequent oxidation) are required: (1) Propanal is formed in large quantities as an intermediate in the production of *n*-propanol [*62309-51-7*] by hydroformylation of ethylene, and (2) the oxidation takes place in plants in which other aliphatic carboxylic acids (*n*-butyric and isobutyric acids, *n*-valeric and isovaleric acids) are also produced. A high utilization of available capacity is therefore guaranteed in both steps.

Propanal Production. The production of propanal is carried out by the hydroformylation of ethylene (→ Propanal, Chap. 4.). It is favored because, unlike the case of the higher aldehydes, *n*/*iso*mixtures cannot be formed.

Two syntheses compete: the classical cobalt-catalyzed high-pressure carbonylation at 200 – 280 bar, and 130 – 150 °C [56], and the rhodium- or iridium-catalyzed low-pressure carbonylation at ca. 20 bar, and ca. 100 °C (→ Carbonylation, Chap. 4.→ Carbonylation, Chap. 4.1.) [57–59].

In the *high-pressure synthesis* the yield is generally impaired by partial hydrogenation of propanal to give propanol. The isolation of the aldehyde takes place, after removal of cobalt, by distillation of an azeotrope with ca. 98 % aldehyde content [56].

In the *low-pressure synthesis* (Union Carbide) [60], the aldehyde can be distilled directly from the reaction mixture in 99 % purity.

Figure 1. Production of propionic acid by the BASF process
a) High-pressure reactor; b) Heat exchanger; c) Separator; d) Expansion vessel; e) Distillation column

Oxidation. Propanal is subsequently oxidized under very mild conditions at 40 – 50 °C to propionic acid with high selectivity (→ Aldehydes, Aliphatic and Araliphatic).

In the United States propionic acid is produced by the oxidation of propanal by Union Carbide and Eastman Kodak (see Chap. 9).

4.3. Direct Oxidation of Hydrocarbons

A large quantity of propionic acid is obtained by the direct oxidation of hydrocarbons, predominantly naphtha. In this process, which is principally used for acetic acid production (→ Acetic Acid, Chap. 4.2.), formic acid [*64-18-6*], propionic acid, and an isomeric mixture of butyric acids are formed as byproducts. Whether this process is considered economic for propionic acid production is principally a question of the market evaluation of the different products. The process has favorable raw material costs, but requires a relatively complex workup of the product mixture [61], [62].

The composition of the acid mixture formed in the oxidation can be affected by the reaction conditions (pressure, temperature), the type of reactor (tubular reactor, column reactor), the raw material (naphtha, liquefied petroleum gas), and by the catalyst [61], [62]. If naphtha is used, the proportion of propionic acid in the mixture is ca. 10 – 15 %. In other cases, e.g., with 2-methylpentane as raw material, the proportion of propionic acid can increase to 31 % [63]. The total yield of acids does, however, vary considerably with the starting material [64–66].

BP Chemicals Process. (Fig. 2) [61], [67]. Naphtha is preheated to 170 °C and oxidized with air at 40 – 45 bar in several reactors (a) in series. The heat of reaction is used for steam generation. The cooled discharge from the reactors is separated from the reaction off-gas in a separator (b). Entrained liquid is recovered from the off-gas and recycled to the reactor; the off-gas is then incinerated. The liquid reactor discharge is separated into an organic phase, which contains unreacted hydrocarbons, and an aqueous phase which contains the product mixture (c). The unreacted hydrocarbons are recycled to the reactor. The low- and high-boilers are separated from the aqueous phase which then gives the crude acid (d). From this the C_1- to C_4-acids are obtained by extractive dehydration (e) followed by fractional distillation (g) – (i).

Propionic acid is produced by direct oxidation at BP Chemicals (UK), Hoechst – Celanese (United States), and Daicel (Japan) (see Chap. 9).

4.4. Construction Materials

The corrosiveness of propionic acid is not only determined by the water content, pressure, and

Figure 2. Production of propionic acid by the BP Chemicals process
a) Reactor; b) Gas – liquid separator; c) Liquid – liquid separator; d) Distillation column; e) Extraction; f) Separation of extracting agent; g) Formic acid distillation; h) Acetic acid distillation; i) Propionic acid distillation

temperature, but also by the degree of purity. The corrosion resistance of the materials used is therefore not always predictable and is frequently dependent on individual conditions.

Ordinary steel is totally unsuitable for the handling of propionic acid. Aluminum is only resistant at room temperature and to anhydrous, concentrated propionic acid; at higher temperature corrosiveness toward aluminum varies with the concentration of acid. Thus the corrosion maximum for 50 °C lies at 75 % acid, whereas there are two maxima at the boiling point, a weaker one at 1 % and a strong one at 99.8 % acid [68].

Copper and copper alloys are stable toward propionic acid up to its boiling point, but only if the solutions are free from air or oxidizing substances [68].

Of the stainless steels, the ferritic chromium steels (13 – 17 % Cr content, UNS no.: S 40 000) are unsuitable because propionic acid tends to cause pitting. Generally, austenitic CrNi steels and CrNiMo steels are used for handling propionic acid. At ambient temperature the CrNi steel X 10 CrNiTi 189 (DIN Materials no. 1.4541, UNS no.: S 30 400) is suitable. The CrNiMo steel X 10 CrNiMoTi 1810 (DIN no. 1.4571, UNS no.: S 31 600) is stable toward pure propionic acid up to its boiling point. However, impurities in propionic acid can make the use of titanium or Hastelloy (e.g., Hastelloy C NiMo 16 Cr 15 W, DIN no. 2.4819, UNS no.: N 10 276) equipment necessary, even below the boiling point [68].

Above the boiling point, up to ca. 230 °C Hastelloy C has shown excellent resistance even under oxidizing and reducing conditions. Above 230 °C only silver has proved to be a suitable material [25].

5. Storage and Transportation

Containers made of aluminum with a purity of 99.5 % (DIN no. 3.0255) or alloyed steels (DIN no. 1.4541/UNS no.: S 30 400 and 1.4571/S 31 600) are suitable for storing pure propionic acid. Aluminum is unstable toward aqueous propionic acid. Polyethylene containers can be used for temporary storage of propionic acid and as small packing drums. Plastics are not recommended for long-term storage. Glass-reinforced plastics are unsuitable even for short-term storage.

According to GefStoffV, propionic acid is classified as “corrosive”, R-phrase 34, and S-

phrase 2-23-26. Transport classification is as follows:

RID/ADR	class 8, no. 32 c
GGVE/GGVS	class 8, no. 32 c
ADNR	class 8, no. 32 c
IMDG Code (D-GGVSee)	class 8
IATA – DGR	class 8 1848
UN no.	1848

6. Quality Specifications

Propionic acid is only sold in pure form with a content of 99.5 wt %, determined acidimetrically. The maximum water content is 0.1 wt %; the sulfate, chloride, and heavy metal content is generally < 1 ppm. The color index is normally below 5 APHA. Oxidizable substances (ketones, aldehydes, esters) can be determined from the reaction time in the $KMnO_4$ test (DAB 7). Their proportions should be < 0.05 wt %.

The standard method for quality control is gas chromatography, e.g., with Chromosorb AW/DM 6 S as the carrier and LAC 446 + H_3PO_4 as the stationary phase. Detection is carried out with a flame ionization detector (FID).

The acid corresponding to the requirements of the Food Chemical Codex (FCC) is given in Table 4 [69].

Table 4. Sales specification of propionic acid [70]

Specification	Limits	Analytical method
Propionic acid content, wt %	99.5	gas chromatography
Water content, wt %	0.1	DIN 51 777
Aldehydes, wt %	0.05	gas chromatography
Readily oxidizable substances, wt %	0.05	DAB 7
Evaporation residue, wt %	0.01	DIN 53 172
Iron, ppm (mg/kg)	1	
Other heavy metals, ppm (mg/kg)	10	
Platinum – cobalt color, APHA	10	DIN 53 409
Density (20 °C), g/cm^3	0.990 – 0.998	DIN 51 757
bp, °C	140.7 – 141.6	DIN 51 751

7. Environmental Protection

Like most lower carboxylic acids, propionic acid is rapidly degraded biologically. The biodegradability in the Zahn – Wellens test is 95 % [71]. The biological oxygen demand for degradation after 5 days (BOD_5) is 1.3 g/g [72] which is 86 % of the total oxygen demand (TOD) of 1.513 g/g. The chemical oxygen demand (COD) is 1.4 g/g [72].

The fish toxicity test with the golden orfe resulted in no mortality with 4000 mg/L propionic acid in 48 h [73]. For the blue gill sunfish (*Leponius macrochirus*) an LD_{50} of 188 mg/L was determined in 24 h [72], for *Daphnia magna* an LD_{50} of 130 mg/L in 24 h and an LD_{50} of 50 mg/L in 48 h [72].

The limiting concentration of bacterial toxicity (*Photobacterium phosphoricum*) is 1240 mg/L [74]. For rats an oral LD_{50} of 3500 mg/kg was determined [73].

On the basis of the toxicity data for the rat, bacteria, and golden orfe, propionic acid is classified in Germany as mildly hazardous to water (WGK 1 = water endangerment class 1) [74].

The growth-inhibiting effect of the non-neutralized propionic acid (DIN 38 412/9) on *Scenedesmus suspicatus* was determined in 96 h as follows (EC = effective concentration and 0, 50, and 90 denote no, 50 %, and 90 % effect, respectively) [75]:

EC 0 = 12 mg/L
EC 50 = 43 mg/L
EC 90 = 79 mg/L

The bioaccumulation in an *n*-octanol – water mixture is log P_{OW} = 0.025/0.33 [72].

In the TA Luft propionic acid is classified in class 2 [76], i.e., if a chemical plant emits a quantity stream of ≥ 2 kg/h, the propionic acid concentration may not exceed 0.1 g/m^3.

The maximum workplace concentrations for propionic acid in Germany (MAK) and in the United States (TLV) in 1992 were 10 mL/m^3 ($\hat{=}$ 30 mg/m^3).

8. Uses

8.1. Use as Food and Feed Preservative

Propionic acid and its salts are broad-spectrum preservatives because of their bactericidal, fungicidal, insecticidal, and antiviral effects, and their acaricidal effect which is found at higher concentrations. Effects at lower inclusion rates

are more of a static nature. Minimum inhibition concentration (MIC) against fungi is 0.05 – 0.50 wt %, against bacteria 0.25 – 0.50 wt %, and against yeasts 0.10 – 1.0 wt % [77]. Efficacy of propionic acid against molds which cause spoilage of organic material such as foods and feeds is pronounced and of particular interest to industry. Gram-negative microorganisms such as *Escherichia coli* and *Salmonella ssp.* are more sensitive to propionic acid than gram-positive microorganisms. Minimum inhibition concentration against *Salmonella typhimurium*, *S. eimsbüttel*, *S. anatum*, *S. enteritidis*, and *S. montevideo* is 1.0 wt % after three days of action [78]. Propionates are ineffective against Salmonella in petri dishes but ammonium propionate and calcium propionate were successfully used to decontaminate Salmonella in meat meal at a 4.5 % inclusion rate with monitoring after four weeks of application [79]. Vaccinia virus was inactivated within 1 h by 1.0 wt % and within 7.5 min by 2.0 wt % propionic acid [80].

Mites in cereals (*Acarus siro*) are killed by 1.0 wt %. A repellent effect is achieved by adding only 0.5 wt % propionic acid. Corn beetles (*Sitophilus granarius*) are killed by 1.0 wt % propionic acid. Development of their eggs is impaired by 0.7 wt %.

Although the mode of action of propionic acid is not yet fully understood, the preservative effect is certainly based on the undissociated acid. At pH 4.88 the undissociated form is present to 50 % and at pH 6.0 to 7 %. This pH range is relevant for practical food and feed preservation. The undissociated acid penetrates into the living cell like a nutrient. Propionic acid inhibits intracellular enzymes which are essential for carbohydrate metabolism [81]. Morphological changes in Salmonella bacteria after treatment with 1 – 3 wt % propionic acid are lysis of the bacteria and loss of flagellum.

The broad efficacy spectrum of propionic acid forms the basis for a wide variety of applications. Its salts must be applied at concentrations equivalent to that of the acid but their effect is slower and not as long lasting. This is because the salts must be hydrolyzed to release the acid. Hydrolysis is incomplete and slow under practical conditions in feeds and foods, e.g., at 15 % moisture content and a pH value between 4 and 6.

Table 5. Application of propionic acid (PA) and its salts as preservatives for foods and feeds ∗

Type of material	Application rate of PA or its salts	Purpose/effect
Bread, bakery products	0.3 % Ca or Na salt; higher concentrations inhibit yeast fermentation	prevention of molds and formation of mycotoxins
Feed grain including corn	0.50 % PA at 16 % moisture 0.65 % PA at 20 % moisture 0.95 % PA at 26 % moisture 1.25 % PA at 32 % moisture 1.50 % PA at 36 % moisture	preservation for 6 months storage; reduction of microorganisms and nutrient losses; inhibition of mycotoxin formation and liberation of free fatty acids; protection from lumpiness and mold
Single feeds and complete feeds	0.2 % PA or 0.4 % salt at moisture level up to 14 %; higher rates at unfavorable conditions	increase of storage time up to 2 months; improvement of weight gain and feed conversion with all types of animal
Feeds of animal origin and complete feeds	0.5 % PA or 0.7 – 0.8 % Ca- or NH_4-salt	reduction of pathogenic flora, e.g., Clostridia, Enterobacteriacea
Feeds of animal origin	1.0 % PA or 2.0 – 3.0 % Ca- or NH_4-salt 2.5 – 3.5 % PA or 4.0 – 6.0 % Ca- or NH_4-salt	protection against recontamination with Salmonella after sterile manufacturing decontamination of heavily infected material
Brewer's yeast, liquid (ca. 10 % dry matter)	1.0 % PA	inactivation of yeast cells; direct feeding is possible after this treatment
Whey, liquid	0.3 % PA	increase of storage time by 2 days
	0.8 – 1.0 % PA	increase of storage time up to 1 week
Silage of grass, corn, and other forage	0.4 % PA for treatment of all material 1.5 – 2.0 L PA/m^2 silage surface, diluted in water by 1 : 4	improvement of lactic acid fermentation; inhibition of butyric and acetic acid producing bacteria; reduction of losses and mold on surface; prevention of nutrient losses

∗ Regulatory status in different countries for foods and feeds must be observed.

Calcium, sodium, and ammonium salts of propionic acid have the advantages of an almost neutral taste and smell. Therefore they can also be applied in food preservation whereas propionic acid is not suitable in this field because its odor is pungent and not acceptable to humans. Most animals prefer the acid taste of feed preserved with propionic acid and increase

their feed intake [82]. A feeding concept for pigs was introduced [83] in which organic acids such as propionic acid are of major importance to control digestion. The organic acids reduce the buffering capacity of feeds and influence the microflora content in the stomach and digestion parameters.

The various uses of propionic acid and its salts are listed in Table 5. Seeds and barley for malting process should not be treated with propionic acid because it inhibits germination.

All aspects regarding application technique, equipment, corrosive effects of propionic acid and propionates, storage and appropriate storage material, dosage, and efficacy are reviewed in [84]. The described effects can only be achieved by homogeneous distribution of the preservative in foods or feeds.

Table 6. Worldwide production capacities in 1989

Producer	Country	Capacity, t/a
BASF	FRG	60 000
Union Carbide	USA	68 000 [a]
Eastman – Kodak	USA	25 000 [a]
BP Chemicals	UK	30 000
Hoechst – Celanese	USA	7000
Daicel	Japan	2000
Total		192 000

[a] Used for production of various carboxylic acids.

Regulatory status of propionic acid and its ammonium, sodium and calcium salts is as follows:

FAO/WHO : ADI is not limited according to WHO Food Additives Series 1974, no. 5.

United States : GRAS status was reconfirmed in 1984 for propionic acid as a preservative for various foods, e.g., bread and other bakery products. The same applies to calcium and sodium propionates. Maximum inclusion rates are limited only by GMP (good manufacturing practice) according to CFR 21, §§ 184.1081, 184.1221, 184.1784 of April 1, 1989.

EC : Approved without upper limit and without specifying any fields of application according to EC Directive of Council 64/54 of Nov. 11, 1963.

Federal Republic of Germany : Approval for food preservation was withdrawn on March 31, 1988; a revision due to EC legislation is expected. According to the German feeds regulations there is no restriction or limitation for using propionic acid and its salts in all kind of feeds (feeds law 1989).

Other countries : There is no other country known in which propionic acid or its salts are not approved for food and feeds.

8.2. Other Uses

Zinc, cadmium, lead, and mercury propionates can be used as vulcanization regulators in rubber production [32].

Propionic acid is used as an intermediate, frequently in the form of its anhydride, for the production of esters. The most important esters are cellulose acetate propionate [*9004-39-1*] (CAP, → Cellulose Esters, Chap. 2.2.), from which thermoplastics are produced, and vinyl propionate (→ Vinyl Esters) which is used as a basic monomer for dispersions [→ Poly(Vinyl Esters)].

Methyl, ethyl, propyl, and butyl propionates are used as solvents for resins and paints [32]. Because of their characteristic fruity aromas various propionate esters are also used in flavors and fragrances.

Small quantities of propionic acid are also further processed to propionyl chloride, which is used as a reactive intermediate for the introduction of the propionyl group in syntheses (e.g., in the production of pharmaceuticals).

Until the end of the 1980s a considerable proportion of propionic acid was chlorinated and further processed to form herbicides (see Chloropropionic acids, Section 11.4). With the arrival of more potent, optically active herbicides and of products with a broader spectrum of activity, the importance of racemic herbicides based on propionic acid has decreased considerably.

9. Economic Aspects

The production capacity in 1989 for propionic acid was 190 000 t/a worldwide. Of this, however, ca. 90 000 t/a were only partially usable for propionic acid, because these plants were also used for the production of other acids. Details

of the distribution of the capacities in 1989 are given in Table 6.

Since 1984 the consumption of propionic acid has been stationary at ca. 130 000 t/a. No change is expected in the near future.

The areas of use of propionic acid and its distribution in 1989 are listed below.

Preserving animal feeds	45 %
Preserving bakery products	10 %
Herbicides	20 %
Plastics	10 %
Pharmaceuticals	10 %
Other	5 %

In the medium-term an increase in its use as a preservative for animal feeds is predicted. In contrast, the use in herbicides will decrease because of the increasing use of optically active substances (see Section 11.4.2.1).

10. Toxicology

Biochemistry, Biokinetics, and Metabolism. Propionic acid, or its metabolically activated form propionyl-CoA, occurs in mammals as a metabolic intermediate in the degradation of odd-numbered fatty acids, the side-chain oxidation of cholesterol, or in the oxidative degradation of certain amino acids (valine, isoleucine, threonine) [85], [86]. The proportion of propionic acid in the volatile fatty acids in the blood (total, contents 0.18 – 1.6 mmol/L) is up to 5 % [85]. Orally administered propionic acid or propionate is rapidly absorbed [87]. This can also be assumed for inhaled propionic acid.

Propionate is rapidly and completely metabolized after activation to propionyl-CoA by means of carboxylation to methylmalonyl-CoA and isomerization to succinate, which then enters the tricarboxylic acid cycle [85], [86]. Thus, conversion rates of 4.5 g propionic acid per hour for the liver of a 70 kg human can be calculated from in vitro investigations on slices of liver [85].

Acute Toxicity. The acute oral and inhalatory toxicity of propionic acid is low (LD_{50} oral rat: 2600 – 4290 mg per kilogram body weight, LC_{50} rat inhalatory $> 19.7\,mg\,L^{-1}\,4\,h^{-1}$). The only study on dermal application showed a higher toxicity (LD_{50} dermal rabbit: 500 mg per kilogram body weight), which may be caused by the strong irritant effect of the substance. Sodium and calcium propionates show a lower oral and a clearly lower dermal action in comparison with the acid [87–91].

Even after intravenous and subcutaneous administration there was no toxicity, but only a sedative effect shortly after the injection [85].

Propionic acid has an irritant/corrosive effect on the skin and an irritant effect on the rabbit eye [88], [89]. Its calcium salt, however, does not show these effects [88].

Subacute, Subchronic, and Chronic Toxicity. When $\leq 5\,\%$ propionic acid or sodium propionate was administered to rats with their feed (estimated substance uptake ≤ 4000 mg per kilogram body weight and day) from 28 days up to the total lifetime of the animals no toxic effects as a whole were found [88], [92–97]. However, with acid concentrations of ca. 0.4 % and higher, local changes in the epithelium of the forestomach occurred, caused by cell proliferation (increase in the basal cell and spindle cell layer). On longer administration, wart-like manifestations and ulcers developed [95], [96], [98]. On administration of 4 % propionic acid in animal feed for 21 days the cell division rate of the forestomach epithelium increased, as measured by ^{3}H-thymidine incorporation [99]. Similar local effects are also known from other short-chain fatty acids such as acetic, butyric, valeric, or caproic acids [92], [95]. Since the forestomach of the rat is a special feature of this species, 90-day investigations on beagle dogs, which have no forestomach, were carried out. Here propionic acid produced a proliferation in the epithelium of the gullet (esophagus), with a no-effect concentration in the feeds of 1 wt %. On feeding with calcium propionate no such effect was found up to the highest concentration used of 4.35 wt % [88].

Genotoxicity (Mutagenicity). In many in vitro investigations with bacteria, yeasts, and cell cultures no indication of a mutagenic effect of propionic acid was found [100–103]. The same applies to sodium [104], [105] and potassium [104] propionates. In vivo investigations on the induction of chromosomal changes by propionic acid in the Chinese hamster [101] or by

sodium propionate in the bone marrow of the rat [105] also gave negative results.

Teratogenicity. Investigations on developmental toxicity of calcium propionate in rats, mice, hamsters, and rabbits (300 and 400 mg per kilogram body weight and day) for 5 – 13 days (duration of test depending on animal species) [90] showed no effects.

Effects on Humans. Taking 6 g sodium propionate orally over several days gave slightly alkaline urine without any further effects [85]. Sodium propionate solutions (10 wt %, pH 7.2) have been used for the treatment of eye infections without irritant effects; 20 wt % solutions (pH 7 – 8.5) did not produce irritation or sensitization of the skin [106].

11. Derivatives

11.1. Salts

Ammonium propionate [*17496-08-1*], $C_3H_9NO_2$, M_r 105.11, is a strongly hygroscopic salt, which melts with absorption of water at 45 °C [107] (*bp* 70 – 75 °C at 1.3 kPa) [108]. Ammonium propionate is being increasingly used in the form of an aqueous solution as a preservative for animal feeds and cut grass.

Sodium propionate [*137-40-6*], $C_3H_5O_2Na$, M_r 96.06, melts at 281 – 284 °C to give an anisotropic liquid [109]. For its production and use see calcium propionate.

Calcium propionate [*4075-81-4*], $(C_3H_5O_2)_2$ Ca, M_r 186.18, crystallizes as the monohydrate in monoclinic plates and as the trihydrate. The anhydrous salt dissolves up to 41.7 wt % in water and is insoluble in ethanol [110]. The aqueous solutions can cause inflammation [111].

Production. The industrial production of calcium and sodium propionates is carried out by the neutralization of propionic acid with the corresponding hydroxides and subsequent spray-drying of the concentrated aqueous solutions.

Uses. Calcium and sodium propionate have fungistatic action. They are added to bread and other bakery products to prevent rope of bread caused by bacteria (Na propionate) and mold formation (Ca propionate). They are used as preservatives for animal feeds and for treatment of ketosis in domestic pets. Mixtures of sodium and calcium salts in an aqueous solution containing 2.5 % propionic acid are recommended for external use in treating mycosis [112].

11.2. Propionic Anhydride and Propionyl Chloride

Propionic anhydride [*123-62-6*], $(CH_3CH_2CO)_2O$, M_r 130.14, is a colorless liquid with an unpleasantly pungent odor, which severely irritates the eyes and mucous membranes. Physical properties are as follows [113]:

bp	167 °C
mp	– 45 °C
Flash point (open cup)	74 °C
Ignition temperature	315 °C
Density at 0 °C	1.0336 g/cm^3
at 50 °C	0.9791 g/cm^3
Kinematic viscosity (20 °C)	1.144 mPa · s
(50 °C)	0.7511 mPa · s

Toxicological data are as follows [114]:

LD_{50} (oral in rats)	2.36 g/kg
Skin (rabbit), irritation dose	500 mg (open, moderate)
Eye (rabbit), irritation dose	750 µg (severe)

Production. Propionic anhydride is produced industrially either by heating propionic acid at 8 bar to 235 °C and distilling off the water formed [115], or by heating propionic acid with propionyl chloride in an inert solvent to 160 °C [116].

Other possible routes involve the reaction of ethylene, carbon monoxide, and propionic acid in the presence of nickel carbonyl (Reppe synthesis [117–120]) or cobalt or nickel iodide [121].

Uses. Propionic anhydride is used as an esterifying agent for fatty acids and cellulose, for the production of alkyd resins and perfume oils, and for the introduction of the propionyl group into dyes and pharmaceuticals.

Propionyl chloride [*79-03-8*], CH_3CH_2CO Cl, M_r 92.53, is a colorless, volatile, and readily flammable liquid, whose vapors hydrolyze in moist air. It is corrosive, lachrymatory, and has a strongly pungent odor. With water and lower alcohols it reacts vigorously under solvolysis to give the acid or ester. Important physical properties are:

bp	80 °C
mp	− 94 °C
Flash point (open cup)	12 °C
d_4^{20}	1.0646

Production. Propionyl chloride is produced industrially by treatment of propionic acid with phosgene [*75-44-5*] or thionyl chloride [*7719-09-7*]. The reaction occurs at ca. 50 °C in the liquid phase in the presence of dialkylformamides. The product is then separated by distillation. Propionyl chloride can also be obtained by the reaction of propionic acid with PCl_5 [*10026-13-8*] [122].

Uses. Propionyl chloride is used for the introduction of the propionyl group and for the synthesis of propionate esters because of its high reactivity.

11.3. Esters

The esters of monohydric alcohols with propionic acid are formed in yields of > 90 % in the reaction of ethylene with carbon monoxide and the corresponding anhydrous alcohols in the presence of $Ni(CO)_4$ at 160 – 200 °C and 50 bar [123], [124].

The *ethyl ester* is also obtained in very good yields by treatment of ethanol with methylketene [*463-51-4*] [125].

Uses. The esters of the $C_1 - C_4$ alcohols are used as solvents for resins and paints [32]. Because of their specific, fruity aromas propionate esters are used as flavorings for foods and in the perfume industry [126]. Some esters and their properties are listed in Table 7.

11.4. Chloropropionic Acid and Derivatives

The 2- chloro- and 3- chloropropionic acids and their derivatives are still important industrially, while 2,2-dichloropropionic acid is virtually no longer used.

2-Chloropropionic acid is produced by direct chlorination of propionic acid, whereas 3-chloropropionic acid predominantly by addition of hydrogen chloride to acrylic acid.

11.4.1. Properties and Production

11.4.1.1. 2-Chloropropionic Acid and Derivatives

2-Chloropropionic Acid. Racemic 2-chloropropionic acid [*598-78-7*], $C_3H_5ClO_2$, is a colorless liquid that is miscible with water and most common organic solvents. Important *properties* are as follows : *bp* (101.3 kPa) 186 °C, *bp* (1.5 kPa) 84 °C; *mp* ca. − 12 °C; vapor pressure at 60 °C 0.4 kPa, at 100 °C 3.0 kPa; density at 20 °C (DIN 51 757) 1.27 g/cm^3 ; flash point (DIN 51 758) ca. 107 °C; ignition temperature (DIN 51 794) > 200 °C; explosion limits 3.7 – 14.3 vol %; water hazard class (WGK) 1 [127]; degradability (DIN 38 412 part 25) > 70 % [127]; TA Luft class I [127].

Commercial grade acid is ca. 95 % pure. The impurities are 2,2-dichloro- and 2,3-dichloropropionic acids, 2- chloropropionic anhydride, and unreacted propionic acid.

Production. 2-Chloropropionic acid is produced by reaction of propionic acid with chlorine at 110 – 120 °C in the presence of acid catalysts such as phosphorus trichloride, thionyl chloride, chlorosulfuric acid, or propionyl chloride [128], [129]. Since the reaction mixture is highly corrosive enamel, silver, glass (or leaded steel) are used as construction materials. One molar equivalent of hydrogen chloride is formed in the reaction and appears in the waste gas. From there it must be isolated and recycled on account of the economy of the process and disposal problems.

Methyl 2- chloropropionate [*17639-93-9*], $C_4H_7ClO_2$, is a colorless liquid that is miscible with almost all common organic solvents. Important *properties* are as follows: *bp* (101.3 kPa) 127 – 129 °C; *mp* < − 10 °C; vapor pressure at 20 °C 0.9 kPa, at 50 °C 4.5 kPa; density at 20 °C (DIN 51 757) 1.14 g/cm^3 ; flash

Table 7. Properties of some propionate esters

Ester	CAS registry no.	Molecular formula	*bp*, °C	Flash point, °C	Aroma/use
Methyl	[*554-12-1*]	$C_4H_8O_2$	79.8	6	rum-like/flavoring, fragrance
Ethyl	[*105-37-3*]	$C_5H_{10}O_2$	99.2	12	butter- or rum-like/flavoring, fragrance
Propyl	[*106-36-5*]	$C_6H_{12}O_2$	121.1	19	pear-like/flavoring, fragrance, solvent
Butyl	[*590-01-2*]	$C_7H_{14}O_2$	145.5	32	Solvent
Isopentyl	[*2438-20-2*]	$C_8H_{16}O_2$	160	41	apricot- or pineapple-like/flavoring, fragrance
Benzyl	[*122-63-4*]	$C_{10}H_{12}O_2$	222	94	jasmine-like/fragrance

point (DIN 51 755) ca. 36 °C; ignition temperature (DIN 51 794) 450 °C; explosion limits 2.8 – 13.9 vol %; water solubility at 20 °C: 22.9 g/L [130]; water hazard class (WGK) 1 [130]; degradability > 60 % [130]; TA Luft class III [130]; LD_{50} (oral, rat) 1080 mg/kg [130]; LC_{50} (by inhalation, rat) 15.3 mg L^{-1} 4 h^{-1} [130].

Methyl 2-chloropropionate is *produced* by esterification of 2-chloropropionic acid with methanol at 40 – 50 °C in the presence of acid catalysts such as sulfuric or hydrochloric acid.

2-Chloropropionyl chloride [*7623-09-8*], $C_3H_4Cl_2O$, is a colorless to pale yellow liquid that is miscible with almost all common aprotic solvents. *Physical properties*: *bp* (101.3 kPa) ca. 110 °C; *bp* (10 kPa) 45 °C; vapor pressure at 20 °C 3.0 kPa, at 60 °C 11.5 kPa; density at 20 °C (DIN 51 757) 1.27 g/cm^3; flash point (DIN 51 755) 34.5 °C; ignition temperature (DIN 51 794) 510 °C.

2-Chloropropionyl chloride is *produced* by reaction of propionyl chloride with chlorine at 70 – 90 °C in the presence of acid catalysts such as sulfuric or chlorosulfuric acid; or by reaction of 2-chloropropionic acid with, for example, thionyl chloride at 60 – 70 °C or with phosgene.

11.4.1.2. 3-Chloropropionic Acid and Derivatives

3-Chloropropionic acid [*107-94-8*], $C_3H_5ClO_2$, forms colorless plates that are readily soluble in water and alcohol; *mp* 41 – 42 °C; *bp* (101.3 kPa) 202 – 205 °C (decomp.); *bp* (2.1 kPa) 108 °C.

3-Chloropropionic acid is *produced* industrially by reaction of acrylic acid with hydrogen chloride at 40 – 45 °C or by reaction of propionic acid with chlorine under UV light at 20 °C [131].

3-Chloropropionyl chloride [*625-36-5*], $C_3H_4Cl_2O$, is a pale yellow liquid with *bp* 144 °C.

3-Chloropropionyl chloride is *produced* by reaction of acrylic acid with hydrogen chloride and phosgene in the presence of, for example, dimethylformamide as catalyst [132], or by reaction of propiolactone with thionyl chloride [133].

11.4.1.3. 2,2-Dichloropropionic Acid

2,2-Dichloropropionic acid [*75-99-0*], $C_3H_3Cl_2O_2$, is a colorless liquid that is miscible with water and alcohols; *bp* (101.3 kPa) 185 – 190 °C; *bp* (1.9 kPa) 90 – 94 °C; *mp* 13 – 15 °C; density at 20 °C (DIN 51 757) 1.40 g/cm^3.

2,2-Dichloropropionic acid is *produced* by reaction of propionic acid or 2-chloropropionic acid with chlorine at $\leq$ 180 °C in the presence of, e.g., phosphorus trichloride [134], thionyl chloride, organic acid chlorides [135], or sulfamic acid [136].

11.4.2. Uses

Chloropropionic acids and their derivatives mainly serve as intermediates. They are used to introduce the propionyl group in the production of biocides, dyes, and pharmaceuticals.

These alkylation reactions take place with elimination of chlorine. In the production of cosmetics and plastics additives the chlorine group in the chloropropionic acid is replaced by other active groups, such as thiol groups.

11.4.2.1. 2-Chloropropionic Acid and Derivatives

Racemic 2-chloropropionic acid and 2,2-dichloropropionic acid have been used predominantly for the production of herbicides. The demand for both acids is decreasing sharply, partly as a result of the development of new herbicides with different chemical structures. 2,2-Dichloropropionic acid is seldom used. Racemic 2-chloropropionic acid is being replaced by the optically active L-enantiomer in the herbicide field.

By far the greatest quantities of 2-chloropropionic acid and its derivatives are still used for the production of *phenoxypropionic acids* (**1**, **2**). Like the phenoxyacetic acids they are highly active herbicides of the growth regulator type [137]. Other derivatives with herbicidal action are phenoxyphenoxypropionates. (**3**) [138], naphthoxypropionamides (**4**) [139] and phenylaminopropionates (**5**) [140].

2-Chloropropionic acid, produced as described in Section 11.4.1, is racemic. Of the phenoxypropionic acids only the D-(+)-isomer shows herbicidal action. Its synthetic precursor is L-(−)-2-chloropropionic acid. Since the 1980s there has been a tendency to produce this class of herbicides from pure L-(−)-2-chloropropionic acid which is available, for example, in the form of its esters. These esters are produced, for example, by chlorination of the corresponding D-lactate esters with thionyl chloride. D-Lactic acid is obtained by a biotechnological process (→ Lactic Acid, Chap. 3.2.).

Activity. Phenoxypropionic acids are predominantly used to combat broad-leaved weeds in grasses, e.g., cereals. The spectrum of activity can, however, be shifted by appropriate substitution. The phenyl ethers of phenoxypropionate esters exhibit selective action towards damaging grasses and do not attack cultivated ones [138].

Dichlorprop or 2.4 DP (**1**) Mecoprop or MCPP (**2**)

Illoxan (**3**)

Devrinol (**4**)

Suffix (**5**)

Trade Names of Herbicides based on Propionic Acid. U-46 range, racemates (**1**, **2**) (BASF), Duplosan range, optically active compounds (**1**, **2**) (BASF), Illoxan (**3**) (Hoechst), Devrinol (**4**) (Stauffer/ICI), Suffix (**5**) (Shell), Fusilade (**6**) (ICI), Verdict (**7**) (Dow).

Fusilade (**6**)

Verdict (**7**)

Esters of 2-Chloropropionic Acid. Methyl 2-chloropropionate is a building block of the fungicide Ridomil (**8**) (Ciba–Geigy) used in plant protection.

Ridomil (**8**)

2-Chloropropionyl Chloride. The Friedel–Crafts reaction of isobutylbenzene with chloropropionyl chloride provides a synthetic route for the antiphlogistic and antirheumatic ibuprofen (**9**).

Ibuprofen (**9**)

11.4.2.2. 3-Chloropropionic Acid

Both 3-chloropropionic acid and its chloride are building blocks for the production of pharmaceuticals such as the antiepileptic beclamide (**10**) and the antitussive oxolamine (**11**) [141]. The acid is also used for the production of 3-mercaptopropionate esters, which are employed as stabilizers, for example in plastics and coatings.

Beclamide (**10**)

Oxolamine (**11**)

11.4.2.3. 2,2-Dichloropropionic Acid

The sodium salt of this acid was formerly an important herbicide (generic name delapon). It is now no longer used in Western Europe and the United States.

Trade Names. Basfapon (BASF), Dowpon (Dow).

11.4.3. Toxicology

Biochemistry, Biokinetics, and Metabolism. The sodium salt of 2-chloropropionic acid is an activator of the pyruvate dehydrogenase complex in both rats and dogs, which results in a lower blood glucose (in rats only), lactate, and pyruvate level. The sodium salt stimulates leucine metabolism in the perfused rat heart [142].

Acute Toxicity. The oral LD_{50} values of 2-chloropropionic acid in rats are in the range 500 – 800 mg/kg [142–144]. The LD_{50} in the mouse (i.p.) is 102 mg/kg [143], and the LC_{50} (rat, inhalation) > 3.38 mg/L at 4 h exposure [143]. Exposure of rats to an enriched or saturated atmosphere of chloropropionic acid (20 °C) leads to their death after an exposure time of more than 2 h [143]. 2-Chloropropionic acid has a corrosive effect on rabbit's skin and an irritant effect on the rabbit's eye [143].

The sodium salt shows a somewhat lower oral and inhalatory toxicity. Its LD_{50} (rat, dermal) is > 2000 mg/kg [143], [145], [146]. The sodium salt is not irritant to the skin but irritates the eye [143]. No sensitizing effects were observed in guinea pigs [143].

Toxicity on Long-Term Exposure. No clinical effects were observed if 0.1 wt % (2-chloropropionic acid) was administered to rats with their feed (estimated substance uptake up to 78 mg/kg per day) over 42 days. Higher concentrations (0.25, 0.5, and 1 wt %) lead to an increased sensitivity and ataxia after the sixth day of administration. Ataxia – reversible in some cases during a recovery period of 36 days – and tremor were observed in the groups that received the higher concentrations. If the *neutralized acid* (neutralizing agent NaOH) was administered at a concentration of 0.04 mol/kg (ca. 0.5 wt %) for 12 weeks, the same symptoms occurred, however, with temporary delay. Foci of necrotic cells in the inner granular cell layer of the cerebellum (concentration 0.25 – 1.0 wt %), atrophy of the testicular germinal epithelium (concentration 0.1 – 1.0 wt %), and thymic lymphoid necrosis (concentration 1.0 wt %) were observed [142]. In another experiment involving rats (concentration in feed 100, 800, and 4000 ppm over 3 months) with the *sodium salt* the same toxic effects occurred. Neurotoxicity and testicular changes were present in the group administered 4000 ppm. At a concentration of 800 ppm only marginal clinical signs of neurotoxicity remained and at 100 ppm no toxic symptoms were observed [143].

Mutagenicity. 2-Chloropropionic acid and its sodium salt showed no mutagenic activity in the Ames test [143], [147].

1. Introduction

Propylene oxide (PO) [*75-56-9*], 1,2-epoxypropane, methyloxirane, is a very reactive substance and one of the most important chemical intermediates.

Since the early 1950s it has become increasingly important to the chemical industry. The demand for PO continues to grow throughout the world; annual worldwide production capacity in 1991 was ca. 3.9×10^6 t and in 1993 it was ca. 4.0×10^6 t.

Today PO is a commodity that can be produced economically only in world-scale plants with capacities of 100 000 t/a or above. It is the starting material for a broad spectrum of products, including polymers (polyurethanes, polyesters), oxygenated solvents (propylene glycol ethers), and industrial fluids (monopropylene glycol and polyglycols).

2. Physical Properties

Propylene oxide, C_3H_6O, M_r 58.081, is a colorless, low-boiling liquid with a sweet, ethereal odor. It is also reactive and highly flammable, with a wide explosive range. Flammable concentrations of vapor form readily at room temperature. Important physical constants are as follows [7–20]:

mp (101.3 kPa)	−111.93 °C
bp (101.3 kPa)	34.23 °C
Flash point	− 37 °C
Critical temperature	209.1 °C
Critical pressure	4920 kPa
Critical density	312 kg/m^3
Critical compressibility factor	0.2284
Autoignition temperature in air at 101.3 kPa	430 °C
Explosive limits in air (STP)	
lower	2.3 vol %
upper	36.0 vol %
Heat of combustion (25 °C, 101.3 kPa)	−33 035 kJ/kg
Heat of polymerization	−1500 kJ/kg
Heat of fusion	112.6 kJ/kg
Heat of solution in water at 25 °C	−45 kJ/kg
Heat of formation of the ideal gas (25 °C)	−1600 kJ/kg
Heat of formation of liquid PO (25 °C)	−2080 kJ/kg
Standard enthalpy (298.15 K)	248 kJ/kg
Standard entropy (298.15 K, 1 atm)	4.94 kJ kg^{-1} K^{-1}
Free energy of formation (25 °C, 101.3 kPa)	459 kJ/kg
Cubic expansion coefficient at 20 °C	0.00151 1/K
Solubility of PO in water at 20 °C	40.5 wt %
Solubility of water in PO at 20 °C	12.8 wt %

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

Dipole moment	2.010 Debyes
Evaporation rate (butyl acetate = 1)	33.7
Molecular diffusion volume	4.937×10^{-5} m^3/mol
n_D^{20}	1.36610
n_D^{25}	1.36335
n_D^{30}	1.36060
Henry constant at 25 °C	8.65×10^{-5} Pa m^3/mol

Table 1 provides temperature-dependent physical properties for both gaseous and liquid PO.

PO has unlimited miscibility with most common organic solvents, but it is subject to a miscibility gap with water (Fig. 1). The binary system PO – water is characterized in Figure 2. This and other binary and ternary vapor-liquid equilibria systems are described in [22].

Figure 1. Miscibility gap and density of the propylene oxide – water system [19]

Figure 2. Phase diagram for the propylene oxide – water system [20], [21]

PO forms azeotropes with dichloromethane, diethyl ether, cyclopentene, isoprene, cyclopentane, 2-methyl-1-butene, pentene, pentane, cyclohexane, hexene, and hexane [22], [23].

PO exists in two optical isomers [24], [25], but commercial PO is a racemic mixture, and it is to this mixture that the listed properties refer.

3. Chemical Properties

PO is a highly reactive, versatile chemical intermediate. Its polarity and the strained three-membered epoxide ring cause it to be opened easily by reaction with a wide variety of substances. In this respect it is analogous to ethylene oxide (→Ethylene Oxide), and the number of possible derivatives is very large.

Most industrial reactions of PO are catalyzed, although PO alone reacts readily with all compounds containing active hydrogen atoms (including the hydrogen halides), as well as chlorine and ammonia. Alkaline catalysts are preferred (e.g., sodium hydroxide, sodium acetate, sodium alkoxide, or potassium alkoxide). Acidic materials, such as sulfuric acid, boron trifluoride, stannic chloride, or acid clays (which are sometimes used at lower reaction temperatures) often form byproducts by converting oxides to cyclic ethers, or by isomerizing them to aldehydes.

The most important type of reaction is the addition of PO to compounds containing labile hydrogen, but it also condenses with a number of substances that do not contain reactive hydrogen.

The most important reaction of PO from a commercial standpoint is its violent polymerization to form poly(ether polyols) in the presence of catalysts such as bases, acids, or salts. Chain initiators are substances containing active hydrogen atoms (e.g., water, glycols, phenols, amines, or carboxylic acids). PO forms mixed polyols with ethylene oxide, tetrahydrofuran, 3,4-epoxy-1-butene (butadiene monoxide), and carbon dioxide.

PO is hydrolyzed by water in an uncatalyzed, liquid-phase reaction to give monopropylene glycol, dipropylene glycol, tripropylene glycol, and polyglycols. PO reacts with ketones or aldehydes to form cyclic ketals or acetals, and with carbon dioxide to form propylene carbonate. Hydrogen halides convert PO to propylene halo-

Extrapolated values are given in parentheses.

hydrins, and ammonia gives mono-, di-, and triisopropanolamine.

Over alumina PO isomerizes to propanal and acetone, and over Li_3PO_4 catalysts to allyl alcohol. Hydrogenation over nickel leads to 1-propanol. Many other reactions are also possible, including reactions with natural products like starch or cellulose. Table 2 summarizes the most important PO reactions.

All the reactions involving PO may become violent if not properly controlled, and possible applications should be investigated very thoroughly.

Under pyrolytic conditions PO isomerizes to propanal, acetone, methyl vinyl ether, and allyl alcohol [26]. Decomposition of PO does not result in hazardous products.

PO is a stable compound under moderate conditions, but polymerization may occur on contact with highly active catalytic surfaces such as iron, tin, or aluminum chlorides, peroxides of iron and aluminum, or alkali-metal hydroxides and clay-based absorbent materials. Anything that destroys the neutrality of PO may also cause polymerization. The chemical stability of PO and its polymerization under storage conditions are discussed in [27].

4. Production and Raw Materials

The selection of production routes is decisively influenced by the application and market potential of coproducts, as well as by availability of raw materials and possibilities for byproduct management [28], [29].

Technologies developed up to this point can be divided into:

1) Chlorohydrin processes (Section 4.1)
2) Indirect oxidation processes (Section 4.2)
3) Direct oxidation processes (Section 4.3)

Only the chlorohydrin and the indirect oxidation processes are practiced currently on an industrial scale. The following sections highlight the various processes and describe in more detail those currently in use (see Fig. 3).

It has so far not been possible to produce PO in a technically and economically satisfactory manner by direct gas-phase oxidation (with silver catalysts) in analogy with the process used for ethylene oxide. All PO processes generate significant amounts of coproducts. For the conventional chlorohydrin process this means up to two moles of salt (sodium or calcium chloride) in the form of dilute brine solution per mole of PO. In the case of the direct oxidation methods, complex organic mixtures arise, which must then be separated via distillation and either sold, further converted, or incinerated. Indirect oxidation technologies also lead to PO and coproducts.

4.1. Production Route via Propylene Chlorohydrin

See also →Chlorohydrins.

Table 2. Summary of the most important PO reactions

Reactant	Product(s)	Structural formula
Polymerization (ROH as initiator)	polyether polyols	$R[-O-\underset{\underset{CH_3}{\vert}}{CH}-CH_2]_n-OH$
Water	monopropylene glycol ($n = 0$) dipropylene glycol ($n = 1$) tripropylene glycol ($n = 2$)	$CH_3-\underset{\underset{OH}{\vert}}{CH}[-CH_2-O-\underset{\underset{CH_3}{\vert}}{CH}]_n-\underset{\underset{OH}{\vert}}{CH_2}$ (and isomers)
Alcohols and phenols (ROH)	propylene glycol ethers	$CH_3-\underset{\underset{OH}{\vert}}{CH}-\underset{\underset{OR}{\vert}}{CH_2}$ (and isomers/highers)
Ammonia	isopropanolamine	$CH_3-\underset{\underset{OH}{\vert}}{CH}-\underset{\underset{NH_2}{\vert}}{CH_2}$ (and isomers/highers)

Isomerization	allyl alcohol acetone propanal	$CH_2=CHCH_2OH$ CH_3COCH_3 CH_3CH_2CHO

Figure 3. Summary of propylene oxide production routes

4.1.1. Chlorohydrin Process

Conventional production of PO is based on the dehydrochlorination of propylene chlorohydrin [*78-89-7*] with a base [30]. Technically, such units are similar to the chlorohydrin units used to produce ethylene oxide (EO) prior to development of the direct oxidation process. Because the demand for PO has increased rapidly, old plants have been steadily improved and new state-of-the-art, grass-roots PO plants have been built throughout the world.

The present commercial chlorohydrin process is carried out in two main steps: synthesis of

propylene chlorohydrin (PCH), and subsequent dehydrochlorination of PCH to PO. These steps are followed by PO purification and wastewater treatment.

Chlorohydrination. In the PCH synthesis reaction (chlorohydrination), propene and chlorine are mixed in an aqueous solution. A propene – chloronium complex is formed as an intermediate (Eq. 1) [31].

The chloronium ion then reacts with water to form hydrochloric acid and the propylene chlorohydrin isomers 1-chloro-2-propanol (90 %) and 2-chloro-1-propanol (10 %) (Eq. 2).

Formation of the chloronium complex is accompanied by two side reactions of chlorine and propene. In the gas phase they react to form the main byproduct, 1,2-dichloropropane (DCP) (Eq. 1.1).

Propene and chlorine also react via 1-chloropropene (allyl chloride) (Eq. 1.2) to give two dichlorohydrin isomers 1,3-dichloro-2-propanol and 2,3-dichloro-1-propanol (DCH 1 and 2, Eq. 1.3).

A simplified overview of all propene-chlorine reactions is thus:

Propene + Chlorine	→ Chlorium ion	→ PCH 1 + PCH 2
	→ DCP	
	→ Allyl chloride	→ DCH 1 + DCH 2

In aqueous solution the chloronium ion can also undergo other reactions, leading to formation of DCP with chloride ions alone (Eq. 2.1) and formation of 2,2′-dichlorodiisopropyl ether (DCIPE) in the presence of PCH (Eq. 2.2).

In a simplified overview, the chloronium ion is therefore responsible for the following reactions:

Chlorium ion	→ + H_2O	→ PCH 1 + PCH 2 + HCl
	→ + Cl_-	→ DCP
	→ + PCH	→ DCIPE

Other chlorinated compounds (e.g., monochloroacetone) are produced in very small amounts. Economic considerations require that coproduct formation be reduced as far as possible by using the best available technology. Based on propene, the most expensive raw material for

the chlorohydrin PO process, modern industrial-scale plants achieve the following yields:

PCH	88 – 96 %
DCP	3 – 10 %
DCH	0.3 – 1.2 %
DCIPE	0.2 – 0.8 %
Others	0 – 1.0 %

Besides the design of the reactors, the amount of water entering into the chlorohydrination has a significant impact on coproduct formation, especially DCP and DCIPE. Excess water has two major effects on side reactions. Firstly, it reduces the propylene chlorohydrin and chloride ion concentrations in the reactor, resulting in less DCP and DCIPE. Secondly, excess water prevents the formation of an organic liquid phase in which chlorine and propene react to form more DCP [32].

Dehydrochlorination. In the second reaction step, dehydrochlorination (also called epoxidation/saponification), the aqueous PCH stream is treated with a base – either lime, $Ca(OH)_2$, or caustic soda (as chlorine cell liquor) – to form crude PO and a dilute $CaCl_2$–NaCl brine stream (Eq. 3).

(3)

In a subsequent reaction a minor part of the resulting PO is hydrolyzed to 1,2-propanediol (monopropylene glycol, MPG) (Eq. 3.1).

(3.1)

Other byproducts formed in the epoxidation step are 1-chloro-2,3-epoxypropane (epichlorohydrin, Eq. 3.2) and its reaction products 3-chloropropane-1,2-diol (glycerol monochlorohydrin, GMCH), 1,2,3-propanetriol (glycerol), propanal, acetone, and 1-hydroxypropanone (acetol).

(3.2)

Chlorohydrination. In a typical commercial chlorohydrin PO process, gaseous propene (either chemical grade, ca. 8 % propane, or polymer grade, ca. 0.3 % propane) and gaseous chlorine are mixed in roughly equimolar amounts with an excess of water to form a dilute solution of PCH (ca. 4 wt %), aqueous HCl, and minor amounts of chlorinated hydrocarbon byproducts, mainly DCP.

Since the reactor design (Fig. 4) is based upon propene and chlorine vapor dispersion into water, and because all reaction products remain in aqueous solution, the role of water is very important. It is used not only as reactant (one mole per mole of propene) and direct cooling medium, but also as a diluent to minimize the formation of byproducts. Numerous patents claim technology for boosting chlorohydrin yields to 90 – 95 % [32–38].

Depending on the capacity of the plant, one or several parallel reactors (a) are used. The reaction temperature varies from 45 to 90 °C, depending on the reactor concept. The exothermic reaction itself raises the temperature by 20 – 30 °C. The operating pressure is usually slightly above atmospheric pressure (1.1 – 1.9 bar). The chlorine : propene ratio must be closely controlled to maintain the proper amount and composition of vent gas. In the separator (b) the reactor vent gas (a mixture of propane, excess propene or chlorine, oxygen, nitrogen, hydrogen, carbon dioxide, PCH, DCP, and other reaction products) is separated from the PCH solution and then fed to a scrubber (c). Vent gas from the scrubber can be sent to a thermal oxidizer to protect the environment and recover energy.

Dehydrochlorination (Saponification). The bottoms from the separator (b) are fed to a saponifier (d) where the PCH is mixed with

Figure 4. Typical arrangement for a propylene oxide chlorohydrin process
a) Propylene chlorohydrin reactor; b) Separator; c) Vent gas scrubber; d) Saponifier; e) Partial condenser; f) Cross exchanger; g) Compressor; h) Propylene oxide purification train; i) Drums

NaOH or lime. The dehydrochlorination of PCH to PO is rapid. Optimum PCH conversion requires a slight excess of alkalinity. Half the base is consumed by neutralization of HCl produced in the chlorohydrination step.

The saponifier has two main functions: (1) conversion of PCH to PO and (2) stripping of organic impurities from the aqueous brine before final treatment in a biological oxidation plant. Crude PO leaves the saponifier as an overhead stream that also contains organic byproducts and water. If lime is used, solids enter the saponifier, so the column should be equipped with trays to minimize fouling. If caustic soda is used, either trays or packing are acceptable. As far as reaction kinetics are concerned [39], an ideal saponifier would be based on the following design criteria:

1) Short residence time in the top to flash PO as quickly as possible, thereby minimizing the formation of MPG
2) A stripping section to minimize PO losses
3) Long residence time to complete the conversion of DCH 2 to epichlorohydrin (DCH 1 conversion is as fast as the PCH conversion)
4) A stripping section to recover epichlorohydrin

These measures ensure that the formation of volatile products is optimized, and that such compounds are removed before subsequent products (e.g., GMCH, glycerol) are formed and lost in the diluted brine. An overall unit-ratio balance is shown in Figure 5.

Purification. After condensation (e – g) the crude PO is sent to distillation towers (h), in the first of which the lights are removed. Bottoms are sent to the finishing column, where PO product is taken off overhead. DCP, DCIPE, epichlorohydrin, and water remain in the bottom for further treatment which depends on the final utilization of coproducts.

Construction Materials. Since chlorine in aqueous solution as well as generated HCl and PCH are extremely corrosive, the construction materials must be selected very carefully[40–42]. The reactor (a), including the last segments of feed lines, separator (b), vent condensers, scrubber (c), saponifier (d), and all related piping are made of corrosion-resistant materials.

Figure 5. Unit ratios for a propylene oxide chlorohydrin process assuming a water – propene ratio of 50 : 1, caustic soda as cell liquor, DCP as the only byproduct, a DCP yield of 5 %, and all steps stoichiometric.

Adequate for the purpose are poly(vinylidene fluoride) fiber reinforced plastics, graphite, rubber- or brick-lined carbon steel, titanium and titanium – palladium alloys; Inconel, Monel, and Hastelloy.

Wastewater. The brine effluents of modern PO plants contain:

1) Ca. 3 – 5 wt % calcium chloride (lime) or ca. 8 wt % sodium chloride (NaOH)
2) Slight excess alkalinity
3) 100 – 400 ppm total organic carbon (TOC)
4) 30 – 60 ppm adsorbable organic halides (AOX)

The main components are MPG and GMCH–glycerol, which are biodegradable. The amount of brine effluent is 30 – 60 kg/kg PO. Downstream final biological treatment systems achieve an AOX reduction of > 85 % (see Chap. 5 for wastewater treatment).

Lime versus Caustic Soda as Alkalinity Source. The chlorohydrin PO process can be operated with caustic soda or slaked lime. Slaked lime is primarily used when chlorine is produced by the mercury or membrane processes (→ Chlorine, Chap. 5.,→ Chlorine, Chap. 7.) to avoid "downgrading" high-purity caustic (Germany, Japan, former Czechoslovakia, and Poland). Caustic is usually used in the form of cell effluent in combination with the diaphragm chlor-alkali process (→ Chlorine, Chap. 6.) since the low-concentration catholyte from such a chlorine cell can be employed directly (United States, Germany). Although this process option in principle allows the spent PO brine to be recycled to the chlorine plant after resaturation, such a recycle system has never been applied at full technical scale. Major hurdles not yet overcome include hydraulic imbalances, as well as sensitivity of the chlor-alkali process to organic impurities. If an integrated diaphragm chlor-alkali site becomes short of NaOH, it is in principle possible to convert the PO process from cell effluent to lime.

Table 3. Comparison of use of lime and sodium hydroxide in the chlorohydrin process [a]

Lime	NaOH (chlor-alkali/PO integrated complex)
+ Frees NaOH for sales (1.4 t/t PO)	+ no caustic evaporator capacity needed ($NaOH/Cl_2 = 1.08$)
− Higher capital investment; additional caustic evaporation capacity, handling, and infrastructure are needed; unloading of CaO, storage, slaker, thickeners, clarifiers, neutralizer, and centrifuges/filter are required	+ lower capital investment and operating cost (no solids handling required)
+ Up to 50 % less discharge of chloride (NaOH as cell liquid containing up to 15 wt % NaCl, wastewater with 5 wt % calcium chloride)	− higher discharge of chloride (wastewater with 8 wt % sodium chloride)
	+/− brine recycle theoretically possible, ca. 15 % more wastewater
− Disposal of separated solids, uncontaminated and contaminated with organics depending on CaO quality	
− More excess alkalinity in wastewater	
− Lime biox technology, dedicated or diluted (problems with $CaCO_3/CaSO_4$ precipitation)	

[a] − denotes disadvantage, + denotes advantage.

A final detailed evaluation of the use of lime relative to caustic soda cannot be made in this article because the parameters to be considered are too diverse, and they are subject to frequent change (e.g., the global alkalinity sup-

ply/demand situation). However, the key advantages and disadvantages are summarized in Table 3 to provide a qualitative overview with respect to economic, environmental, technological, site, and site-integration issues.

Figure 6 provides a block diagram of a PO–lime process.

One very important issue is the quality of the calcium oxide used for the lime process. Normally, it has a purity of 85 – 95 wt %. The MgO and SiO_2 contents should be kept as low as possible to minimize solids handling.

4.1.2. Other Chlorohydrin Technologies

Modified chlorohydrin technologies have been proposed [29], but they are not currently applied on an industrial scale:

1) The formation of propylene chlorohydrin in two process steps using *tert*-butyl hypochlorite as a chloride-free chlorine-transfer agent (Lummus process)
2) Electrochemical production of PO–the formation of propylene chlorohydrin and subsequent dehydrochlorination to the oxide take place in chlor-alkali electrolysis cells
3) Electrochemical production of PO, in which the formation of propylene chlorohydrin and dehydrochlorination to the oxide occur outside chlor-alkali membrane electrolysis cells

All three process modifications are designed to permit complete recycle of PO brine to the chlor-alkali cells at constant or even reduced DCP byproduct levels. Achieving a balance of the requisite countercurrent conditions leads to (1) increased complexity of the unit operations (e.g., large, complex cascade reactors) and/or (2) high operating costs (e.g., energy-intensive distillation due to a low PO concentration in the catholyte). Furthermore, the selectivity with respect to DCP is at best comparable to that obtained with existing chlorohydrin technology. In fact, DCP formation is likely to be increased, and other chlorinated byproducts (e.g., chloroacetone) may be formed at the expense of DCP. Finally, the sensitivity of chlorine cells to organic contaminants in the concentrated recycle brine must be taken into account. The disadvantages of these process modifications are high in terms of both investment and energy costs.

Propylene Chlorohydrin with Recycle (Lummus Process). One chlorohydrin PO process not currently operated on an industrial scale uses *tert*-butyl hypochlorite instead of chlorine. This allows recycling of the major portion of the aqueous process streams. Process water from the hypochlorination can be recycled to the propylene chlorohydrin reactor. Brine, produced during saponification, can be appropriately treated and recycled to the chlorine cells. Resaturation is not required.

This integrated chlor-alkali/PO process is balanced on water; i.e., kg water in = kg water out. The level of organic byproducts is comparable to that of standard chlorohydrin technology. Lummus has several patents that disclose the technology of such a closed-loop process [43–45].

tert-Butyl hypochlorite is prepared from cell effluent, chlorine, and *tert*-butanol (Eq. 4). The key difference relative to established chlorohydrin processes results from the fact that *tert*-butyl hypochlorite is insoluble in water. It therefore separates as an organic phase from the aqueous brine solution and can be isolated by means of a phase separator. Consequently, propene can be hypochlorinated with *tert*-butyl hypochlorite in an aqueous system, thereby avoiding the presence of chloride ions (Eq. 5).

$$\mathrm{Cl_2 + NaOH + \textit{tert}\text{-}C_4H_9OH} \rightarrow \mathrm{\textit{tert}\text{-}C_4H_9OCl + NaCl + H_2O} \tag{4}$$

$$\mathrm{\textit{tert}\text{-}C_4H_9OCl + H_2O + C_3H_6} \rightarrow \mathrm{C_3H_6OHCl + \textit{tert}\text{-}C_4H_9OH} \tag{5}$$

$$\mathrm{C_3H_6OHCl + NaOH \rightarrow C_3H_6O + NaCl + H_2O} \tag{6}$$

No contact occurs between the chloronium complex and chloride ions (see page 5), so the ratio of water to propene in the process can be reduced without a concurrent increase in the level of byproducts. Furthermore it is possible to recycle a major portion of the nearly chloride-free process water to the front end of the chlorohydrin reactor. Because of the lower water consumption, the two brine solutions–one resulting from *tert*-butyl hypochlorite formation step (Eq. 4) and the other from the hydrolysis of propylene chlorohydrin to PO (Eq. 6)–are close to saturation. They

Figure 6. Block diagram for the PO/lime process

can be recycled to a chlorine cell after removal of organic impurities by chlorinolysis.

By contrast, in the conventional chlorohydrin PO process it is essential to minimize reaction between the chloronium complex and chloride ions, because this leads to the formation of DCP. The high ratio of water to propene required to suppress this undesirable side reaction means that the aqueous brine streams have salt concentrations too low to permit complete recycle to the chlorine cells (see Section 4.1.1). A major disadvantage of the Lummus process is the slowness of the reaction between *tert*-butyl hypochlorite and propene. Huge, titanium-clad cascade reactors are required. The presence of an additional component (*tert*-butyl alcohol) also leads to a more complex byproduct spectrum. The treatment of recycle streams is very energy intensive, and investment costs for the process are high.

4.2. Indirect Oxidation Routes

Several reaction routes and process alternatives for the production of PO by indirect oxidation have been reported in the patent literature, but only a few are practiced on an industrial scale. Indirect oxidation is a two-step process:

1) Formation of hydrogen peroxide or an organic peroxide from a suitable alkane, aldehyde, or acid
2) Conversion of the peroxide to water or the corresponding alcohol or acid by epoxidation of propene to PO

Epoxidation of Propene with Hydrogen Peroxide. The epoxidation of propene can be accomplished with hydrogen peroxide in the liquid phase and in the presence of, for example, a molybdenum-based catalyst. Subsequent reactions can lead to formation of considerable amounts of glycols and glycol esters, and thus to separation problems [46–53]. One process modification, published by Enichem [54], makes use of a titanium silicate catalyst in a methanol – water mixture at 40 – 50 °C and a propene pressure of 4 bar. PO selectivities of 75 – 97 % are reported. Disadvantages of this process are the considerable hazard potential associated with concentrated H_2O_2 solutions and high H_2O_2 production costs.

Epoxidation of Propene with Peroxycarboxylic Acids. The required peroxy acids can be prepared by different routes. For example, peracetic acid can be formed by oxidation of acetaldehyde with air or oxygen, or by reaction of acetic acid with H_2O_2. See also →Peroxy Compounds, Organic, Chap. 4.2.

Organic peracids such as performic acid, perphthalic acid, permaleic acid, perpropionic acid,

and peracetic acid react with propene to give PO and the corresponding carboxylic acid. The rate of epoxidation depends on the type of solvent used. Peracetic and perpropionic acids are the preferred epoxidizing agents, and no catalyst is required.

If the starting material for production of peroxyacetic acid is acetaldehyde, the coproduct acetic acid must be removed from the production loop. Process economics depend strongly on the demand for acetic acid and its value to industry. Process experience with a 12 500 t/a plant is available at Daicel; the yield of PO is 90 %. Typically 1.3 kg of acetic acid is produced per kg of PO [55–69]. Scaleup of this technology to industrial capacities ($\geq$ 100 000 t/a) is expensive and difficult, and the value of acetic acid is not sufficiently high to justify the process on a large scale.

The Bayer – Degussa process starts from acetic or propionic acid and H_2O_2, and proceeds via peracetic or perpropionic acid, respectively. The acid coproduct can be recycled to the front end of the process. PO selectivities $\geq$ 95 % can be reached.

A common disadvantage of all processes based on H_2O_2 is that safety considerations require H_2O_2 production facilities to be restricted in size. Economic large-scale production of H_2O_2 for the production of PO is not possible with today's processes.

Coproduct Processes. Oxidation of propene with organic hydroperoxides in the presence of catalysts has developed into a successful indirect oxidation route to PO. Half the world PO production is now based on this route [70–101]. Various organic hydroperoxides can be used (Table 4).

Organic hydroperoxides are generated by catalytic oxidation of appropriate substrates with air or oxygen. Because of coproduct value and market demand, the *tert*-butyl hydroperoxide and ethylbenzene hydroperoxide routes are those practiced in industry.

The production of PO by indirect oxidation with organic hydroperoxides requires two steps. The *tert*-butyl alcohol or α-phenylethanol coproducts formed in parallel with PO are of considerable economic value, because they can be converted to methyl *tert*-butyl ether [*1634-04-4*] (MTBE) or styrene [*100-42-5*], respectively, in subsequent reaction steps. When styrene or MTBE is in great demand, coproduct process economics are competitive with those of the alternative chlorohydrin production routes. The coproducts are always formed in larger amounts than PO itself. In the case of the process with *tert*-butyl hydroperoxide, 2.5 – 3.5 kg of *tert*-butyl alcohol are formed per kilogram of PO. The ethylbenzene process produces 2.2 – 2.5 kg of styrene per kilogram of PO. Obviously, the presence of these coproducts can also become a disadvantage if the demands for PO and the respective coproduct are not properly balanced, requiring that PO production capacity be restricted as demand for the coproduct weakens. No such considerations apply to the chlorohydrin processes. A regional limitation of the coproduct processes results from raw material logistics. Especially for the *tert*-butyl hydroperoxide process, economic operation requires integration into a refinery complex, where mixed butanes and ethylbenzene are readily available.

Process with tert-Butyl Hydroperoxide. The main reactions in this process are:

Figure 7 shows a simplified flow scheme for the PO – *tert*-butyl alcohol process. Isobutane is generated by isomerization of a mixed butane fraction. This is then converted with oxygen at 120 – 140 °C and 25 – 35 bar in an epoxidation reactor to *tert*-butyl hydroperoxide, which partially decomposes to *tert*-butyl alcohol [28]. This reaction takes place in the liquid phase and does not require a catalyst; however, additives can be used to optimize reaction conditions. Isobutane conversion is ca. 48 % at a selectivity of 50 % relative to hydroperoxide and 46 % relative to *tert*-butyl alcohol.

The crude peroxide solution is used for the epoxidation of propene. It consists of a mixture

Table 4. Reaction systems for PO – coproduct synthesis [70]

Raw material	Peroxide	Intermediate	Coproduct
Acetaldehyde	peracetic acid		acetic acid
2-Propanol	peracetic acid	acetone	2-propanol
Isobutane	*tert*-butyl hydroperoxide	*tert*-butyl alcohol	isobutene
Isopentane	*tert*-pentyl hydroperoxide	*tert*-pentyl alcohol	isoprene
Ethylbenzene	ethylbenzene hydroperoxide	α-phenylethanol	styrene
Cumene	cumene hydroperoxide	dimethylphenylmethanol	α-methylstyrene
Cyclohexene	cyclohexene peroxide	cyclohexanol	cyclohexanone

Figure 7. Flow scheme for PO – *tert* butyl alcohol

of *tert*-butyl hydroperoxide, *tert*-butyl alcohol, and smaller amounts of aldehydes and ketones. This is mixed with a homogeneous catalyst, dissolved in toluene; propene is added, and the mixture is fed to the epoxidation reactor system. The preferred catalyst is a molybdenum salt. Epoxidation is accomplished in a staged reaction system consisting of up to five consecutive reactors. The liquid-phase reaction is carried out at 110 °C at ca. 40 bar in the first part of the reactor system. In the second part the temperature is elevated to 120 °C to complete conversion of the hydroperoxide. The selectivity of the converted peroxide to PO is ca. 80 % with a 10-fold excess of propene; i.e., not all the peroxide reacts to form PO. It may decompose without transferring oxygen to propene. Propene conversion reaches ca. 9 % per pass, of which 98 % is converted to PO. Crude PO is then distilled from the reaction mixture and finished. The bottoms of this distillation consist of a mixture of *tert*-butyl alcohol, catalyst, and medium- and high-boiling components.

The crude PO contains hydrocarbons, carbonyl compounds, and ethylene oxide as impurities, which must be removed by rectification and extractive distillation. For further purification of the carbonyl-free PO rectification with *n*-octane is suggested; the overhead product is pure PO. The hydrocarbons present in the crude PO are successively removed from the *n*-octane, which is then reused.

The *tert*-butyl alcohol can be dehydrated to isobutene and then converted to methyl *tert*-butyl ether (MTBE), which is of significant use as a fuel additive for lead-free gasoline. See also

→ Methyl Tert-Butyl Ether. Educt – product ratios are shown below:

Educts:	2.90 kg isobutane
	0.88 kg propene
Products:	2.98 kg *tert*-butyl alcohol
	0.15 kg acetone
	1.00 kg PO

Process with Ethylbenzene Hydroperoxide. The main reactions of this process are:

Figure 8 shows a simplified flow sheet of the process, based on patent data. A more detailed flow scheme has been published by Chem Systems Inc. [5].

In the first process step ethylbenzene is reacted with air at 146 °C and 2 bar to give a 12 – 14 wt % solution of ethylbenzene hydroperoxide in ethylbenzene. The reaction takes place in the liquid phase. For safety reasons conversion is restricted to 10 %. The reactor configuration suggested in [102] consists of up to nine separate reaction zones, over which the temperature is reduced from 146 °C to 132 °C by controlled recycle gas addition to avoid decomposition of the peroxide. The resulting peroxide solution in ethylbenzene is mixed with a homogeneous molybdenum catalyst (Halcon) and propene [103]. Alternatively, a heterogeneous titanium-based catalyst can be used (Shell). The latter offers a similar performance, but may be easier to separate from the product stream [104].

For the Halcon route the reaction mixture consists of 100 parts peroxide solution, 2 parts molybdenum naphthenate, and 30 parts propene. Epoxidation of propene is carried out at 100 °C and 35 bar. The crude product stream contains PO, α-phenylethanol, acetophenone, propene, and other organic impurities. Catalyst removal requires a wash with aqueous alkali and phase separation. Propene can be recycled after distillation. Crude PO is purified by distillation. The finishing is similar to that in the *tert*-butyl hydroperoxide route. Ethylbenzene is recovered for recycle from the bottoms of the PO distillation. The remaining α-phenylethanol-rich mixture, which still contains up to 15 % acetophenone, is fed to a dehydration reactor and mixed with an alumina catalyst and triphenylmethane as process solvent. Thermal treatment at 270 °C and 0.35 bar leads to dehydration. Styrene is obtained with a selectivity of 98 %.

α-Phenylethanol and acetophenone are the main byproducts. Educt – product ratios for this process have been reported by Chem Systems Inc. [5]:

Educts:	2.11 kg benzene
	0.76 kg ethylene
	0.88 kg propene
Products:	2.54 kg styrene
	1.00 kg PO

4.3. Direct Oxidation Routes

There is no direct oxidation process for producing PO that is close to commercialization. Difficulties in controlling temperature variations over fixed catalyst beds are among the several hurdles preventing satisfactory selectivity for PO. Nevertheless, construction of a pilot plant has been announced for a new direct oxidation process involving a molten nitrate salt as catalyst [105]. An advantage of this particular direct oxidation variant may be the potential for maintaining a constant reactor temperature (454 °C) in the molten salt bed. However, in addition to PO, several byproducts arise in substantial amounts, including methanol, acetaldehyde, carbon dioxide, ethylene, and formaldehyde.

The breakthrough in direct oxidation of propene to PO has not yet been achieved. For commercial PO production during the next ten years, the only alternatives are the chlorohydrin process or coproduct technologies.

4.4. Comparison of the Various Propylene Oxide Technologies

Direct comparison of the chlorohydrin PO process with the PO/*tert*-butyl alcohol or

Figure 8. Flow scheme for PO – styrene process
a) Separator; b) Recycle column; c) Crude PO column; d) Ethylbenzene recycle column

PO/styrene coproduct process is very difficult, as the technologies are too diverse and have different objectives. For a PO producer with no market for the coproduct it is obvious that there is currently no alternative to the chlorohydrin PO process. A producer able to include MTBE or styrene in the product portfolio must decide whether a coproduct process or two independent plants represents the preferred solution with respect to economics, demand balances, and geographic flexibility. The fact that stand-alone units for chlorohydrin PO, styrene, and MTBE are still being announced and built indicates that the PO coproduct process is not always economically superior. A comparative economic model of chlorohydrin versus coproduct PO processes is presented in [5]. A decision in favor of one PO production route or the other also depends on the infrastructure, location, and integration of a particular site. Thus, a chlorohydrin PO process can be operated most economically if it is integrated within a chlor-alkali plant. The MTBE process requires integration into a refinery complex. The effluent load of a chlorohydrin PO plant is larger than that of a coproduct plant, so extensive water treatment facilities are required, and the salt load means that an environmentally acceptable geographical location (close to the sea) is desirable. On the other hand, the fire and explosion risk with a PO coproduct plant is significantly greater than in the case of a chlorohydrin facility, and product flexibility is considerably more limited with a coproduct plant than with a stand-alone process.

5. Environmental Protection and Ecotoxicology

Propylene oxide is recognized as a toxic substance (Chap. 10), so specific measures must be taken to avoid environmental pollution during PO production. Critical issues associated with water discharge, air emissions, and handling of PO are discussed briefly below.

Wastewater. State-of-the-art technology for wastewater treatment requires that chlorinated organic compounds first be separated via rectification, stripping, or extraction. The stream is then sent to a biological oxidation unit for eliminating biodegradable compounds like propylene glycol.

In the past, large concrete ponds were often used as aeration basins, but more and more companies are installing biotowers. Significant advantages of such towers include:

1) Higher efficiency
2) Greatly reduced space requirements
3) Less danger of ground water contamination
4) Easier collection and treatment of the vent

The most critical parameters related to water discharge are:

1) Salt discharge at "upstream sweetwater" sites (chlorohydrin process only)
2) Total organic carbon (TOC)
3) Chemical oxygen demand (COD)
4) Adsorbable organic halides (AOX)
5) Temperature
6) Solids disposal (separated as filter cake)

Off-Gas. Environmental legislation varies considerably from country to country, one of the strictest being that in Germany. Discharge to the atmosphere of vent streams with a mass flow $\geq$25 g PO/h is permitted in Germany for PO concentrations up to 5 mg/m^3 [106], [107]. Normally, however, such streams are incinerated with state-of-the-art thermal oxidizers.

For a chlorohydrin PO process, thermal oxidizer treatment is required for the reactor vent, noncondensables in the crude PO, lights from the purification, and tank vent streams. Fugitive emissions represent the only remaining emission source.

In the coproduct processes it is advisable to use oxygen instead of air, since this reduces the volume of vent gas subject to treatment.

Fugitive Emissions. Fugitive emissions are caused mainly by: leaking mechanical seals of pumps, gaskets, and stuffing boxes of valves.

PO is not known to occur naturally. It has been suggested that, apart from PO production facilities, PO may be introduced into the atmosphere from combustion exhausts of sources that burn hydrocarbons [108], [109]. In the atmosphere PO reacts with photochemically produced hydroxyl radicals and has an estimated half-life of 19.3 d. PO is not expected to contribute to ozone depletion [110], [111]. In water, PO is hydrolyzed to propylene glycol with an estimated half-life of 11.6 d at 25 °C and pH 7. The chloride ions in salt water accelerate the chemical degradation to a half-life of 4.1 d [109]. PO is practically nontoxic to fish on a static acute basis (LC_{50} >100 mg/L) [112–116]. Biodegradation of PO under aerobic static laboratory conditions is high (BOD_{20}/ThOD = 74.7 %, where ThOD means theoretical oxygen demand). The biochemical oxygen demand (BOD) of PO is 0.35 g O_2/g PO and 1.65 g O_2/g PO for 5 d and 20 d, respectively [107].

PO evaporates relatively rapidly from dry soil surfaces, and it is moderately volatile from water and wet soils, but the evaporation rate is diminished by leaching. PO is expected to be very mobile in soil. In moist soils hydrolysis is the most significant degradation process. No appreciable concentrations of PO are expected to be found in the environment or aquatic organisms [118].

6. Quality Specifications and Analysis

PO obtained from different processes (Chap. 4) displays consistently high purity (>99.9 %; see Table 5). The quality of the propene feed contributes significantly to the impurity content in the final product. Polymer-grade propene is preferable to reduce formation of acetaldehyde and ethylene oxide. Acetaldehyde causes problems in polyol applications, whereas ethylene oxide leads to undesirable contaminants in propylene glycol.

Other impurities may also be present depending on the nature of the production process (e.g., chlorinated organic compounds, hydrocarbons, ethers, aldehydes, acetone, methanol, butanol, *tert*-butyl alcohol, or furan).

Quality specifications are becoming increasingly strict, and customer satisfaction can best be assured by instituting statistical quality tools.

PO and its process-specific coproduct spectrum (e.g., aldehydes, chlorinated organic compounds, methanol, acetone, hydrocarbons, and ethers) can be determined by gas chromatography. Water can be analyzed by the Karl-Fischer method (DIN 51 777, ASTM D 203). The platinum – cobalt standard is used as a color reference (DIN 53 409, ASTM D 1209).

Table 5. Typical specifications for PO in urethane applications

Parameter	Chlorohydrin process	PO/*tert*-butyl alcohol process	PO/styrene process
Purity, %	99.9	99.9	99.9
Color (APHA)	10	10	10
Water, mg/kg	100	100	100
Aldehydes, mg/kg	30	30	30
Total chlorides, mg/kg	30	30	30
Methanol, mg/kg	not present	50	not present
Furan, mg/kg	not present	not present	50

Processes are monitored with on-line gas chromatographs and, more recently, with IR systems.

7. Handling, Storage, and Transportation

Detailed attention is required on issues of safety, health, and the environment. Product stewardship policies provide the basic tools for managing these vital business activities. For example, in 1988, the U.S. Chemical Manufacturers Association (CMA) adopted a "Responsible Care" program; details are provided in [119], [120]. Based on these principles, many companies have developed new product stewardship policies; e.g., [121].

Handling. Safety precautions related to the handling of PO (e.g., protective clothing, sampling, vessel entry, loading, unloading, and general issues) are described in detail in data sheets provided by the manufacturers [122], [123] and elsewhere [124]. Therefore, only the most important issues are discussed in this article.

Personnel handling PO must receive appropriate training. PO reacts readily with all compounds containing active hydrogen. Contact with materials such as acids, bases, oxidizing materials, and clay-based absorbents must be strictly avoided.

Spills, Leaks, and Fire. In case of a spill, leak, or fire the following measures should be taken:

1) Shut off all potential ignition sources.
2) Dilute liquid spills with copious amounts of water (H_2O : PO ratios $\geq$200 : 1). Use water spray to reduce the extent of vapor. The effectiveness of such a spray can be checked by testing the area with an explosimeter.
3) Maintain the water spray, and shut off the flow of PO to the leak.
4) Do not shut off the water until it is certain that the leak has stopped and that flammable concentrations have dissipated.
5) Prevent runoff from entering sewers and/or natural waters.
6) Adequate fire extinguishing media include water, alcohol foam, CO_2, and dry powder.
7) Small fires (e.g., at a pump-seal leak) can be extinguished with a fire hose, deluge gun, CO_2, or dry powder.
8) Large fires (e.g., from a blown gasket) present a different and more serious problem. Do not attempt to extinguish the external fire, or to shut off the feed to the fire. Instead, change the nature of the feed to the fire. Start filling the container with water or nitrogen and continue to fill at a rate adequate to maintain pressure on the leak. With sufficient water or nitrogen dilution, fuel to the fire will be cut off from the inside, or the fire will be extinguished as a result of creating a nonflammable mixture. Water should be sprayed on all adjacent oxide- or flammable-containing equipment to keep it cool. Once the fire is out, the entire area should be sprayed with water to reduce the chance of reflash.

Storage. Storage tanks for PO are usually made of ASTM A-516 grade steel or stainless steel. Because of the tendency of PO to polymerize, all equipment should be absolutely free of impurities. Therefore, PO tanks are constructed in such a manner that they can be completely drained and cleaned.

Tanks and piping systems must be purged with nitrogen to reduce their oxygen content to < 0.5 vol % [automatic N_2 pad and depad system (N_2 inertization)]. Pure N_2 should be used (max. 100 ppm O_2).

Fragile devices (e.g., glass or plastic sight and gauge glasses as well as expansion joints and flexible or screwed connections) should be avoided in PO service. Teflon spiral-wound stainless steel gaskets are preferred. Flat graphite and/or EPR rubber gaskets are also acceptable.

All equipment containing liquid PO should be protected with automatic deluge or sprinkler systems. The maximum storage temperature should be 35 °C.

Tanks and facilities for loading and unloading PO should be equipped with spill-retention walls or dikes (remotely drained) to direct spills into containment areas. Such catch basins should suffice for 110 % of the tank capacity, or be large enough to accomodate an adequate volume of deluge water.

The use of insulated tanks should be avoided because experience shows that corrosion underneath the insulation creates the potential for a spill. Other relevant safety considerations (e.g., minimum instrumentation) are described in [122], [123].

Transportation. PO is transported in gravity or gas ships, railcars, tank trucks, and containers. Hazard classifications and transport information are listed in Table 6.

Emergency response organizations, e.g., the "TUIS" (Transport Unfall Informationssystem) in Germany, have been established to provide local authorities with adequate information and help when requested. Special emergency response and transportation equipment data sheets (Tremcards) are available [125].

The European Chemical Industry Council (CEFIC) has approved a project called "International Chemical Environment" (ICE) in which emergency response will be further improved through close cooperation between national chemical federations, fire brigades, local authorities, and national emergency response centers. The goal is to provide professional assistance all over Europe in case of distribution incidents involving chemicals.

In order to achieve maximum conveyance safety the following minimum requirements for transportation equipment are recommended (Dow Chemical).

Sea Barges and Gravity Gas Vessels. For detailed information, see [126], [127]:

1) If a vessel under consideration is in nondedicated service, tanks and associated piping should be effectively cleaned to remove all traces of previous cargos and rust before PO is loaded. All tanks must be entered for final inspection.
2) Documentation must be provided for the three most recent cargos. No materials known to catalyze reactions of PO (e.g., acids, alkalis, amines, or ammonia) are permitted among the previous three cargos.
3) Independent vapor return should be used during loading and unloading.
4) Cargo tanks (on gravity ships, for example) with a design pressure of less than 0.6 bar (gauge) should be equipped with a cooling system to maintain PO far below its boiling point. Use of such a cooling unit is not required in colder regions of the world and on journeys of less than seven days.
5) Piping systems for tanks that are to be loaded with PO should be completely segregated from piping systems for all other tanks (removal of spool pieces and installation of blind flanges).
6) For other important points see the Section above on Storage.

Railcars. Design according to RID (Europe), AAR (USA), and GGVE (Germany). Top-loading/unloading nozzles are preferred, protected by a thick (2.5 cm) heavy-duty dome in the event of a roll over.

Tank Trucks. Design according to ADR (Europe), DOT MC 330/331 (USA), GGVS (Germany). Valves should be located at one side and in front of the rear wheels. Heavy-duty protection is recommended for the bottom line and valves.

Containers. Type 5 vessels (liquefied gas under pressure) are recommended for PO service.

Table 6. Hazard classifications and transport information for propylene oxide [a]

Transport mode	Codes according to legal requirements				Danger class	Label
	International	Europe	United States	Germany		
Sea	IMO/IMDG			GGVSee	3.1 UN no. 1280 page no. 3047	3
Barge				ADNR		
Rail		RID [b]	AAR	GGVE	3-2(A)	3
Road		ADR [b]	DOT	GGVS	3-2(A)	3
Air	ICAO/IATA				3 UN no. 1280	LF

[a] Sample shipment not allowed by post.
[b] ADR/RID hazard identification: (Kemler Code) 33-1280 (UN no.).

Valves should be located at the bottom (both sides), protected by an adequate safety system.

Other important criteria for railcars, tank trucks, and containers are that the maximum allowable working pressure should be at least 5 bar, design pressure at least 10 bar. Recommended minimum wall thickness is 6 mm.

8. Uses

PO is an important basic chemical intermediate. Virtually all the PO produced is converted into derivatives, often for applications similar to those of ethylene oxide (EO) derivatives (→Ethylene Oxide, Chap. 9.).

PO is used primarily to produce polyether polyols, propylene glycols, and propylene glycol ethers. The distribution of PO applications (derivatives) in the U.S. market is shown below, and is typical for the world market [128]:

Polyether polyols comprising	
Flexible foams	51 %
Rigid foams	10 %
Nonfoam uses	7 %
Propylene glycols	22 %
Glycol ethers	4 %
Miscellaneous	6 %

Most of the PO produced (65 – 70 %) is used as an intermediate for *polyether polyols* that are mainly consumed in the manufacture of polyurethanes. Polyurethanes can be prepared with a wide range of hardness, rigidity, and density characteristics (→Polyurethanes). Flexible polyurethane foams are important in furniture and automobile seating, bedding, and carpet underlay. They are made from polyols with molecular masses >3000. Polyols with lower molecular masses lead to rigid foams for such applications as thermal insulation. Polyether polyols used in polyurethanes are based on di-, tri-, or polyhydric alcohols. They are usually PO/EO-copolymerized, with a PO content of ca. 70 wt % for rigid and 90 wt % for flexible foams.

Homo- or copolymerized polyethers are also used as surface-active agents in detergents, textiles, defoamers, hair-care preparations, brake fluids, and lubricants. Increasing the PO/EO ratio causes a surfactant to become more hydrophobic. Polypropylene glycols with molecular masses in the range 400 – 4000 are produced by polyaddition of PO and a difunctional alcohol. Polypropylene glycols become less hydrophilic with increasing molecular mass. Nonpolyurethane applications include lubricants for rubber; in metal rolling, drawing, and machining; antifoaming agents; in deicing formulations for gasoline; and in hydraulic fluids.

Propylene glycols constitute the second largest application for PO. Monopropylene glycol (MPG) is the direct reaction product of PO with water (→Propanediols). Di-, tri-, and higher propylene glycols are coproduced by the reaction of MPG with PO. Propylene glycol is consumed mainly as a raw material for unsaturated polyester resins, especially for the textile and construction industries. It is also used as a humectant, and as a solvent and emollient in food, drugs, and cosmetics. Further uses relate to coatings, plasticizers, heat transfer and hydraulic fluids, antifreezes, and aircraft deicing fluid. Applications of propylene glycol have benefitted from its lower toxicity relative to ethylene glycol. Di- and tripropylene glycols are

used in hydraulic and drilling fluids, in cutting oils, and as lubricants. The main advantage of the polyglycols is their biodegradability.

Propylene glycol ethers are formed by the reaction of PO with alcohols, usually methanol, ethanol, propanol, or butanol. Certain traditional ethylene glycol ethers and their acetates are being replaced by their PO-based analogues. The demand for PO-based glycol ethers and acetates is therefore growing rapidly, and now constitutes the third largest market for PO (ca. 4 %). Typical applications include solvent use in coatings, paints, inks, resins, cleaners, waxes, and electronic circuit board lamination. The glycol ethers are also found in heat-transfer fluids and anti-icing agents for jet fuel.

Various *specialty organic compounds* can be derived from PO, including allyl alcohol (glycerol synthesis), propylene carbonate (a specialty solvent for organic and some inorganic compounds), mono-, di-, and triisopropanolamines (detergent raw material), and hydroxypropylated cellulose.

9. Economic Aspects

PO is a raw material for major consumer goods in virtually all industrialized countries, and it occupies third place in the consumption of total propene (ca. 10 %) after polypropylene and acrylonitrile. Because of continuing expansion of its field of application, PO production was forecast to increase (see Table 7).

Until 1969 essentially all the PO was produced by the chlorohydrin process. A plant using a version of the peroxidation process (indirect oxidation) was started by Arco in the United States in 1969. In 1991 ca. 50 % of world PO-production capacity was based on the chlorohydrin process, with the remainder coming from peroxidation (Table 7). Dow Chemical and Arco Chemical are dominant in PO production, representing more than 80 % of world capacity. World production of PO in 1992 was ca. 3.2×10^6 t/a, with an expected annual growth rate of ca. 4 %.

Table 8 provides an overview of PO production capacities. The technical, economic, and environmental aspects of large-scale PO production are discussed in [5], [29].

10. Toxicology and Occupational Health

Extensive experience has shown that PO can be handled safely provided appropriate precautions are taken. However, because of its toxicity, PO should be handled only by persons familiar with the hazards involved and willing to observe appropriate precautions.

In general, the health hazards of handling PO are associated with vapor inhalation and eye and skin contact.

Oral Toxicity. The acute oral toxicity of PO is moderate. LD_{50} values have been reported for rats, mice, and guinea pigs in the range 300 – 1000 mg/kg [129], [130].

Skin Contact. PO has only a low to moderate potential for absorption through the skin in toxic amounts. The dermal LD_{50} for skin absorption of PO in rabbits and guinea pigs is 1240 mg/kg [130] and 7200 mg/kg [131], respectively. PO is not irritating to the skin if allowed to evaporate freely, but contact for several minutes may result in mild local redness [132]. Aqueous solutions are more irritating than undiluted PO. More sustained contact results in the development of chemical burns, blistering, and swelling [133], [134].

Eye Contact. High vapor concentrations of PO are irritating to the eye. Liquid PO has caused serious local injury to the eyes of laboratory rabbits [135]. Cases of corneal burns have been reported in humans [129]. Permanent impairment of vision, even blindness, may result from such contact. Affected eyes should be immediately flushed with flowing water for at least 15 min.

Inhalation. Exposure to PO at several hundred ppm may result in headache, dizziness, drowsiness, nausea, chest discomfort, and cough [134]. Higher concentrations (>1000 ppm) may lead to edema, irritation to the respiratory tract, and loss of consciousness [136], [137]. One case of human poisoning resulted from vapor exposure to 1500 ppm for 10 min. Recovery from this poisoning incident occurred the following day [138].

Inhalation studies with laboratory animals suggest a "no-adverse-effect level" for all

Table 7. Comparison of global PO production capacities, consumption, and process shares

PO production	1986	1991	1996 [a]

species of 150 ppm [129]. No evidence of neurotoxicity was detected in male rats exposed to PO by inhalation for 24 weeks at a level of 300 ppm [17].

At exposure levels ≥4000 ppm PO is considered to have mild central nervous system effects in animals, characterized by ataxia, uncoordination, and general depression [133], [139].

The odor threshold in air is 200 ppm (95 % confidence limit: 114 – 353 ppm) [137], a value too high to prevent accidental overexposure. Nevertheless, the sweet, penetrating odor may be sufficient to signal the danger of acute exposure.

Teratogenicity. PO does not produce teratogenic effects in laboratory animals before or during gestation. In rats, fetotoxicity has been seen only at doses high enough to cause toxic effects to the mother. In rabbits, exposure has not proven substantially toxic either maternally or with respect to the fetus [140].

Mutagenicity. PO directly alkylates proteins and DNA, induces gene mutations in all microorganisms tested, and induces chromosomal aberrations in mammalian cells in vitro [141–147]. In vivo, an increased frequency of micronuclei was induced in mice after intraperitoneal PO exposure, but not after oral administration, even at near-lethal doses. No clear dominant lethal effects were found in rodents or monkeys [142], [148]. No chromosomal abnormalities or effects on the sister chromatid exchanges were observed in monkeys exposed for two years [139], [149], [150].

Carcinogenicity. Lifetime inhalation studies on laboratory rats and mice suggest a weak carcinogenic effect of PO in animals at high dose levels [151–156], but the evidence for carcinogenity in humans is inconclusive [157–159]. Evaluations of toxicity to warm-blooded species are described in [160]. PO has been classified by the U.S. Environmental Protection Agency as a class B-2 substance (probable human carcinogen) [159], and it is listed as a group III carcinogen in the German TA Luft [107].

Permissible Exposure Limits. PO is recognized as a toxic substance by the International Agency for Research on Cancer (IARC), and is classified as a class 2A carcinogen (TLV-TWA = 48 mg/m^3 = 20 ppm) [139]. The German MAK commission has listed PO as a group III A2 carcinogen (TRK = 6 mg/m^3 = 2.5 ppm) (at 20 °C/1013 hPa: 1 ppm = 2.42 mg/m^3).

Prostaglandins are formed from *arachidonic acid*. Those and all other derivatives of arachidonic acid, e.g., prostacyclins, thromboxanes, leukotrienes, and lipoxines are called eicosanoids. Most eicosanoids are chemically and metabolically unstable. Therefore, many pharmaceutical companies have tried to improve the stability by modifying the original structures. Several of these analogues have already reached the market in different therapeutic indications or show promising results in clinical trials. This article describes the chemical and pharmacological properties of the natural derivatives and their analogues as well as the synthetic access to some of the natural compounds.

1. History

Prostaglandins (PG) are a group of compounds formed in animals and humans that are derived from unsaturated C_{20} carboxylic acids. The physiological action of these compounds was described independently by U. S. VON EULER and M. W. GOLDBLATT as early as 1933/34 [37]. However, it was not until 1960 that S. BERGSTRÖM isolated pure $PGF_{1\alpha}$ and PGE_1 [38] and, a few years later, elucidated their structures [39]. Prostaglandins of the D series (PGD) were first characterized in 1966 [40]. The prostaglandin endoperoxides (PGG_2, PGH_2) [41] (1974, B. SAMUELSSON), thromboxane (TXA_2) [42] (1975, B. SAMUELSSON), and prostacyclin (PGI_2) [43] (1976, J. R. VANE) were presumably the last important derivatives of the cyclooxygenase pathway to be found.

In 1979, B. SAMUELSSON discovered another biosynthetic pathway that started from unsaturated C_{20} carboxylic acids, the lipoxygenase pathway [44]. The derivatives of the 5-lipoxygenase pathway are called leukotrienes (A–F). The physiological action of a mixture of some of these substances (then called SRS = slow reacting substances) was described in 1938 by W. FELDBERG and C. H. KELLAWAY [45]. Their absolute configurations were finally assigned by E. J. COREY and B. SAMUELSSON in 1980 [46].

In 1984, the structurally very closely related lipoxines were discovered by B. SAMUELSSON [47]. S. BERGSTRÖM, B. SAMUELSSON, and J. R. VANE received the Nobel Prize in 1982 for their extensive work.

2. Structure, Nomenclature, and Physical Properties

Prostaglandins are formed from *arachidonic acid.* All derivatives of arachidonic acid, e.g., prostaglandins, thromboxanes, leukotrienes, and lipoxines are called *eicosanoids.*

Arachidonic acid

The nomenclature of the *prostaglandins* (PG) is based on the hypothetical compound prostanoic acid [48]; the numbering of the carbon atoms is continuous and starts at the carboxyl group:

© 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a22_261.pub2

Prostanoic acid

The prostaglandins are classified (A–J) on the basis of the functional groups attached to the cyclopentane ring:

Additional numerals 1, 2, or 3 (subscripts) refer to the number, position, and stereochemistry of the double bonds in the side chains of the natural prostanes. Prostaglandins of the 1 series possess a double bond with an *E* configuration between C-13 and C-14. Those belonging to the 2 series have an additional double bond with a *Z* configuration between C-5 and C-6. Those of the 3 series possess a further double bond with a *Z* configuration between C-17 and C-18 (Table 1).

The subscript α denotes ring substituents on the same side as the carboxyl chain and β, on the opposite side. The *thromboxanes* (TX) have a tetrahydropyran ring instead of the cyclopentane ring of the prostaglandins.

Thromboxane A_2

[*57576-52-0*] (TXA_2)

Thromboxane B_2

[*54397-85-2*] (TXB_2)

No uniform basic structure exists for the closely related *leukotrienes* (LT) and *lipoxines* (LX). These compounds are all polyunsaturated, open-chain carboxylic acids. Similar to the prostanes, the numbering of the carbon atoms starts at the carboxyl group. The letter in the name of these compounds indicates the configuration and the position of the double bonds. The numerals refer to the number of double bonds. The 14, 15 double bond with the *Z* configuration is missing in the leukotrienes of the 3 series, and an additional double bond with a *Z* configuration in position 17 exists in compounds of the 5 series.

Lipoxine B_4 [*98049-69-5*] (LXB_4)

Physical Properties. Many of the natural prostaglandins, leukotrienes, and lipoxines are oils or solids with low melting points. Thus, they have to be characterized by spectroscopic methods (^{1}H- and ^{13}C-NMR, UV, and IR spectroscopy; mass spectrometry). Radioimmunoassays (RIA) based on antigen–antibody binding are most suitable for the determination of several prostanes and leukotrienes in biological media, because of their high sensitivity and selectivity. The stable metabolites of the prostanes are normally measured to obtain reproducible results.

PGE_1, $C_{20}H_{34}O_5$, M_r 354.49, *fp* 115–116 °C, $[\alpha]_D = -55°$ (tetrahydrofuran), UV spectrum after base treatment: λ_{max} (methanol) 278 nm, ε = 25 350 L mol^{-1} cm^{-1}.

PGE_2, $C_{20}H_{32}O_5$, M_r 352.47, *fp* 64.5–65.5 °C, $[\alpha]_D = -61°$ (tetrahydrofuran).

$PGF_{1\alpha}$, $C_{20}H_{36}O_5$, M_r 356.51, *fp* 101–103 °C, $[\alpha]_D = +30°$ (ethanol).

$PGF_{2\alpha}$, $C_{20}H_{34}O_5$, M_r 354.49, *fp* 30–35 °C, $[\alpha]_D = +24°$ (tetrahydrofuran).

PGA_2, $C_{20}H_{30}O_4$, M_r 334.46, viscous oil, $[\alpha]_D = +140°$ (chloroform).

PGD_2, $C_{20}H_{32}O_5$, M_r 352.47, *fp* 58–59 °C, $[\alpha]_D = +9°$ (tetrahydrofuran).

PGI_2 sodium salt, $C_{20}H_{31}O_5Na$, M_r 374.45, *fp* 116–124 °C (capillary), *fp* 166–168 °C (block), $[\alpha]_D = -124°$ (95 % ethanol), hygroscopic.

LTB_4, $C_{20}H_{32}O_4$, M_r 336.47, *fp* 25–28 °C, $[\alpha]_D = +13.1°$ (deuterochloroform), UV spec-

trum: λ_{max} (methanol) 260, 269, 281 nm, ε = 39 000, 53 000, 43 000 L mol^{-1} cm^{-1}.

LXA_4 methyl ester, $C_{21}H_{34}O_5$, M_r 366.50, $[\alpha]D = +38.2°$ (methanol), UV spectrum: λ_{max} (methanol) 284, 296, 309 nm.

LXB_4 methyl ester $C_{21}H_{34}O_5$, M_r 366.50, colorless waxy solid, $[\alpha]D = +19.2°$ (chloroform), UV spectrum: λ_{max} (methanol) 275, 287, 301, 315 nm.

Most eicosanoids have a very low chemical and metabolic stability (metabolic instability means that the biological degradation is high). For instance, PGE_2 is only stable at pH 7; below pH 7 it is converted to PGA_2, above pH 7 it is converted to PGB_2. Pure PGI_2 has a half-life of a few minutes and is hydrolyzed to 6-oxo-$PGF_{1\alpha}$. The sodium salt of PGI_2 is, however, sufficiently stable for transportation at low temperatures.

While $PGF_{2\alpha}$ is stable enough, it is advisable to store and transport the leukotrienes and lipoxines in alcoholic solution, in a cool place, and as far as possible under exclusion of oxygen.

TXA_2 decomposes within a few minutes to give TXB_2. Hence, only stable TXA_2 analogues are commercially available.

3. Occurrence and Biosynthesis

Eicosanoids occur almost ubiquitously in animals and humans. The concentrations depend on the type of tissue and are generally very low (ca. 1 µg/g wet weight). Prostaglandin concentrations in human seminal fluid are especially high (300 µg/mL).

The occurrence of eicosanoids in corals is of interest. *Plexaura homomalla,* a marine soft coral found in the Carribean, contains the 1-methyl ester of 15*R*-PGA_2-15-acetate in relatively large amounts (1–3 % of the dry weight) and the corresponding 15-epimer in smaller amounts [49]. Furthermore, new prostanoid structures called clavulones and punaglandins have been isolated from *Clavularia viridis* and *Telesto riisei*, respectively [50] (see Table 2). These compounds are of interest because they exhibit antitumor activity.

Prostaglandins also occur in plants [51]. The ubiquitous presence of these arachidonic acid derivatives in living organisms, their wide spectrum of activity, and high potency indicate that they play a central physiological role.

The enzyme phospholipase A_2 (PLA_2) releases arachidonic acid from reserves (mainly phosphatidyl choline) in the lipids of the cell membranes. The biosynthesis of prostaglandins and thromboxanes of the 2 series proceeds via PGH_2, which is formed from arachidonic acid by the enzyme cyclooxygenase (see Fig. 1).

The prostanes of the 1 and 3 series are synthesized from the corresponding unsaturated C_{20} carboxylic acids (dihomo-γ-linolenic acid or eicosapentaenoic acid).

Since 1990 a novel class of prostaglandin-like compounds, the isoprostanes, is known, the members of which may play a role as mediators of oxidant injury in vivo. Newer results indicate that they may be responsible for important biological effects in the lung and in the kidney as well. Isoprostanes are produced by a free radical process and in contrast to prostanes the stereochemical arrangement of the two side chains at the cyclopentane ring is *cis* [52].

8-*iso*-$PGF_{2\alpha}$

[*27415-26-5*]

8-*iso*-PGE_2

[*27415-25-4*]

The key compound in the biosynthesis of leukotrienes is LTA_4, which is formed from arachidonic acid by the enzyme 5-lipoxygenase. LTA_4 is then converted to LTB_4 by a hydrolase and to the leukotrienes C_4–E_4 by glutathione-*S*-transferase and further degradation (Fig. 2).

Arachidonic acid can be converted to lipoxines [53 – 55] by the combined action of 15- and 5-lipoxygenase (see Fig. 2).

The eicosanoids formed locally from the released arachidonic acid exert their specific, selective action via receptors [56], causing intracellular changes in the concentration of cyclic AMP and inositol triphosphate. Using the methods of molecular biology several eicosanoid receptors and their subtypes have been charac-

Table 2. Clavulones and punaglandins

	Punaglandin 4	[*96055-66-2*]

terized and some of them have been cloned (see Table 3). The major importance of natural prostaglandins lies in the autocrine and paracrine regulation of physiological and pathological processes.

The biosynthesis of prostanes, leukotrienes, and lipoxines can be influenced by inhibitors of cyclooxygenase (nonsteroidal anti-inflammatory drugs, NSAIDs), and lipoxygenase [57, 58]. Aspirin, for example, causes irreversible inhibition of cyclooxygenase and ibuprofen reversible inhibition. This inhibition is responsible for the antiphlogistic activity of these two compounds. See also, → Anti-inflammatory–Antirheumatic Drugs.

Since 1991 it has been known that cyclooxygenase exists in two isoforms COX-1 and COX-2 [59 – 62]. Whereas COX-1 is responsi-

Figure 1. Biosynthesis of prostaglandins and thromboxanes from arachidonic acid

ble for the biosynthesis of prostaglandins under normal physiological conditions, COX-2 is expressed mainly in inflammatory tissue, causing the synthesis of prostaglandins which support this inflammation.

Under physiological conditions COX-2 is present for example in the brain and in the kidney but not in the gastric mucosa. Based on these findings three novel COX-2-selective NSAIDs have been introduced on the market as antirheumatic drugs with lower side effects: Celebrex (celecoxib, Pfizer) [*169590-42-5*], Vioxx (rofecoxib, Merck) [*162011-90-7*], and Bextra (valdecoxib, Pfizer) [*181695-72-7*]. However, in 2004 Merck withdraw Vioxx voluntarily because of safety concerns. In 2005 Pfizer withdraw Bextra because of cardiovascular problems and allergic skin reactions.

Nevertheless, a discussion is ongoing about the return of the drugs to the market.

Figure 2. Biosynthesis of leukotrienes and lipoxines from arachidonic acid

Valdecoxib

The 5-lipoxygenase inhibitor *zileuton* [*111406-87-2*] (trade name Zyflo) was introduced by Abbott as an anti-asthmatic and anti-inflammatory drug (→ Antiasthmatic Agents, Chap. 5).

Zileuton

4. Pharmacological Effects and Uses

Eicosanoids exert different pharmacological effects on different organs. The high intrinsic activity at the site is accompanied by rapid metabolic inactivation (e.g., by 15-, β-, or ω-oxidation). The only effects of the structures in the cyclooxygenase and lipoxygenase pathways that are discussed here are those that are of possible therapeutic interest.

Reproduction. Prostaglandins of the E and F series contract uterine smooth muscle and are therefore suitable agents for the induction of parturition or abortion. As a result of their effects on other smooth muscle organs and consequent side effects (headache, nausea, vomiting, diarrhea),

Table 3. Classification of prostanoid receptors

these compounds are seldom given systemically to induce labor. Even local application (intraamniotic, vaginal) is accompanied by side effects.

A combination of prostaglandin and antigestagen has proved useful for inducing abortions for medical reasons because it is tolerated better than an antigestagen alone [63].

Another economically important application of prostaglandins (mainly of the F series) is in veterinary medicine. Their luteolytic activity (the ability to induce the regression of the corpus luteum) is exploited for the induction of ovulation and synchronization of the menstrual cycle in cows, pigs, sheep, and horses.

Lungs. Prostaglandins of the E and I series administered as an aerosol dilate the smooth muscles of the bronchial tract and antagonize bronchoconstriction caused by histamine. In spite of these effects, the development of a prostaglandin agent for treating asthma has not been possible so far.

However, it was found that prostacyclin analogues are suitable for the treatment of pulmonary hypertension [87]. This disease is one of the most serious chronic disorders of pulmonary circulation. It is characterized by constriction of the pulmonary blood vessels, leading to an increased blood pressure in these vessels. Since the pulmonary arteries narrow progressively in the course of the disease, the right heart is forced to pump even harder against this resistance. The increasing demand on the heart muscle eventually leads to right heart failure. The first inhaled stable prostacyclin analogue on the market for the therapy of this disease was iloprost (Ventavis).

The healthy lung has almost no 5-lipoxygenase activity, whereas formation of leukotrienes and thromboxane A_2 is increased in the asthmatic lung. The bronchoconstricting effects of LTC_4 and LTD_4 are 1000 times that of histamine. The development of selective LTC_4/D_4 antagonists or inhibitors of the 5-lipoxygenase pathway [64] have therefore proven useful in asthma therapy and some of these compounds have reached the market (→ Antiasthmatic Agents, Chap. 5). Antagonists of LTB_4 and TXA_2 have also been tested for this indication. Newer results indicate that there may be a potential to treat also the inflammatory component of cardiovascular disease with leukotriene modulators [88].

Stomach and Intestine. The outstanding significance of the prostanes (E, A, and I types) in the gastrointestinal tract is based on their inhibition of gastric acid secretion and their cytoprotective effect [65]. Cytoprotection here refers to the ability of prostaglandins, in very low concentrations, to protect the gastrointestinal tract against harmful noxious agents, e.g., nonsteroidal anti-inflammatory agents (aspirin etc.). This property is probably based on an increased formation of mucous membranes and improvement of circulation.

One of the main applications of prostaglandin derivatives is in ulcer therapy. Faster healing of peptic ulcers has been observed after the administration of PGE analogues [66] (→ Antiulcer Drugs, Section 3.4.1). In contrast to cytoprotection, relatively high doses are required to inhibit gastric acid production and thus achieve healing. Diarrhea is an undesirable side effect.

In patients suffering from ulcerative colitis, raised levels of LTB_4 and, to a lesser extent, PGE_2 and LTC_4 have been observed [67]. This indicates a possible therapeutic use of LTB_4 antagonists.

Heart and Circulation. (See also, → Cardiovascular Drugs, Section 5.3) Prostaglandins of the E and A series lower blood pressure (hypotensive effect) in humans. In contrast, $PGF_{2\alpha}$ and TXA_2 increase blood pressure because they constrict blood vessels.

Prostacyclin, the natural antagonist of thromboxane A_2, also exerts a hypotensive effect, but its inhibition of platelet aggregation is more important.

The use of prostacyclin mimetics for thrombosis prophylaxis or thrombolysis [68] (e.g., peripheral circulatory disorders, Raynaud's syndrome) is based on this effect. Although less active than PGI_2, PGE_1 is also used for the same indication. Side effects include headache, nausea, flush, and diarrhea.

Despite there has been a lot enthusiasm for the TXA_2 antagonists [69] only few of the development candidates have reached the market so far. The discovery of novel compounds acting as TXA_2-antagonist while activating the PGI2 receptor [89] may be an interesting development.

Analogous to cytoprotection in the stomach, a cardioprotective effect of PGE_1 and prostacyclin has been proposed. This could lead to the application of these compounds for prophylaxis of heart attacks.

PGI_2 mimetics may prove useful in alleviating changes produced by arteriosclerosis because the level of prostacyclin synthetase in healthy vessel walls decreases with progressing arteriosclerosis [70].

Kidneys. PGI_2 and PGE_2 cause renal vasodilation and stimulate kidney circulation [71]. In addition, prostaglandins are involved in the excretion of salt and water. Their influence on other hormones (e.g., angiotensin II) is also of significance.

In the kidney, arachidonic acid is also metabolized by another enzyme system (epoxygenase pathway). The importance of the resulting metabolites in renal circulation has not yet been clarified [72].

Cerebral Effects. TXA_2 and $PGF_{2\alpha}$ contract brain vessels, whereas PGI_2 has a dilatory effect. The use of PGI_2 mimetics [73] and TXA_2 antagonists [74] in cerebral infarctions has therefore been discussed.

With the development of new neuroprotective prostacyclin analogs, e.g., (15R)-16-*m*-tolyl-17,18,19,20-tetranorisocarbacyclin (called 15R-TIC) [90], it was possible to differentiate between the known prostacyclin receptor (now named IP1) and a potential novel prostacyclin receptor subtype named IP2. Iloprost demonstrates high-affinity binding to IP1 in the caudal medulla (nucleus of the solitary tract, NTS) but only weak affinity for the IP2 receptor. Isocarbacyclin showed similar affinity for both IP1 and IP2 subtypes and 15R-TIC (isocarbacyclin with a modified lower side chain) binds only to the novel CNS specific IP2 receptor subtype expressed in the rostral brain region. Such new type of prostacyclins may have an impact in the field of neuroprotection.

15R-TIC [*175169-68-3*]

Much higher concentrations of PGD_2 are found in the brain than in other tissues. The equilibrium between PGD_2 and PGE_2 in brain tissue apparently plays an important role in the sleep–wake cycle [75].

Miscellaneous Effects. A higher capacity for prostaglandin synthesis is found in human tumors than in normal tissue. Prostanes are involved in tumor growth and metastasis. However, PGI_2 and mimetic agents exert an antimetastatic effect on melanoma cells, probably due to their strong antiaggregation effect [76]. Although the mechanisms of action are still unclear, there is hope that a therapeutic effect will be obtained by influencing the arachidonic acid cascade [77].

An interesting discovery is the fact that prostaglandins of the F and D series are capable of reducing intra-ocular pressure, and thus represent additional therapeutics for glaucoma [78].

In 2001 a novel PGD-type prostanoid receptor named CRTH2 (chemoattractant receptor-homologous molecule expressed on TH2 cells, sometimes also named as "DP2" receptor) was identified, which displays different functions than the classical DP receptor [91]. Pharmacological characterization suggests an important role for the CRTH2 in allergic diseases and other pathophysiological conditions. Ramatroban, which has been originally developed as a TXA_2 antagonist and is marketed for seasonal allergic rhinitis, has a mixed receptor profile and is also an antagonist for CRTH2. Several companies are now looking for selective CRTH2 antagonists and their potential for antiallergic drugs.

In psoriasis, increased levels of LTB_4 have been found in inflamed areas of the skin [79]. LTB_4 seems to be involved in other inflammatory processes as well (e.g., rheumatic diseases) [80].

LTB_4 is assumed to be an important mediator of inflammation. It is a very effective chemotactic agent for neutrophilic leukocytes, i.e., the white blood cells move in the direction of increasing LTB_4 concentrations and release lysosomal enzymes which attack not only the inflamed, but also neighboring healthy tissue. LTB_4 antagonists may therefore be therapeutically useful as new antiphlogistic agents.

In contrast to the leukotriene antagonists or enzyme inhibitors the lipoxins [92] exert their anti-inflammatory potential by activating the endogenous signalling pathways by which inflammation is normally resolved. Novel lipoxins analogs such as 15-epi-17,18,19,20-tetranor-17-*p*-fluorophenoxy-LXA_4 have shown their anti-inflammatory activity in several animal model related to inflammatory bowel disease, psoriasis, and asthma. Nevertheless, none of these compounds has been tested in human studies so far. Therefore the future will show the potential of such compounds in the aforementioned diseases.

15-epi-17,18,19,20-tetranor-17-*p*-fluorophenoxy-LXA_4 [*205176-29-0*]

The natural eicosanoids are normally not considered for therapeutic applications because of their rapid metabolic degradation and their wide spectrum of activity. Modified derivatives are therefore synthesized to improve not only the selectivity, but also the metabolic stability of these compounds.

A selection of prostaglandin, prostacyclin, thromboxane, and leukotriene derivatives is presented in Tables 4 5 6 7 8, respectively. They include therapeutic agents that have already been introduced to the market and compounds that are still the subject of research and development.

Economic Aspects. The economically most important applications of eicosanoids are the treatment of cardiovascular, gastrointestinal, pulmonary, ophthalmic and gynaecological diseases.

For example, 5 % of men over 50 suffer from peripheral circulatory disorders. Of these 10 % develop a critical phase, i.e., 25 % will lose a limb and 20 % will die within one year. These patients strongly benefit from treatment with commercially available prostanes (e.g., Alprostadil, Epoprostenol, Iloprost, Beraprost).

Another example is the use of prostaglandins in patients with arthritis who must be treated with NSAIDs over a long period. About a quarter of them suffer from gastric ulcers which develop as a result of the daily intake of these drugs.

Table 4. Uses of prostaglandins in human and veterinary medicine

Structure	Generic name, CAS registry no.	Originator	Trade name or phase of development	(Potential) indication
	cloprostenol sodium [*55028-72-3*]	Zeneca	Estrumate	synchronization of menstrual cycle in cows
	prostalene [*54120-61-5*]	Syntex	Synchrocept	synchronization of menstrual cycle in domestic animals
	dinoprost [*38562-01-5*]	Pharmacia & Upjohn	Minprostin $F_{2\alpha}$	termination of pregnancy
	dinoprostone [*363-24-6*]	Pharmacia & Upjohn	Minprostin E_2	termination of pregnancy
	sulprostone [*60325-46-4*]	Schering AG	Nalador	termination of pregnancy
	gemeprost [*64318-79-2*]	ONO	Gervagem	termination of pregnancy, initiation of menstruation
	enprostil [*73121-56-9*]	Syntex	Gardrin	antiulcer
	misoprostol [*59122-46-2*]	Searle	Cytotec	antiulcer
	ornoprostil [*70667-26-4*]	ONO	Ronok	antiulcer
	rosaprostol [*56695-65-9*]	IBI	Rosal	antiulcer

Table 4. Continued

	alprostadil [*745-65-3*]	Schwarz Pharma, ONO	Prostandin, Prostavasin	arterial circulatory disorders
	limaprost [*74397-12-9*]	ONO	Opalmon	peripheral circulatory disorders
	latanoprost [*130209-82-4*]	Pharmacia & Upjohn	Xalatan	glaucoma
	unoprostone isopropylester [*120373-24-2*]	Ueno	Rescula	glaucoma
	bimatoprost [*155206-00-1*]	Allergan	Lumigan	glaucoma
	travoprost [*157283-68-6*]	Alcon	Travatan	glaucoma

Prostaglandins (e.g., Misoprostol or Enprostil) prevent these injuries effectively.

In the future additional eicosanoid derivatives may be suitable for treating certain cancers [93] and inflammation diseases (e.g., psoriasis).

5. Syntheses

Many different syntheses exist for the compounds of the cyclooxygenase and lipoxygenase pathways (Chap. 2). A large number of these syntheses are described in numerous review articles and monographs [1 — 32]. Three basic strategies of synthesis that are exemplary for the prostaglandin field are presented here, followed by the first synthesis of the natural substances PGI_2, TXA_2, and LTB_4. All these syntheses yield not only the natural substances, but also allow the synthesis of analogues. Some of these methods are now used for industrial production.

Synthesis of $PGF_{2\alpha}$ According to E. J. COREY (Fig. 3). E. J. COREY was the first to develop a method for a stereocontrolled access to natural prostaglandins [81]. The cyclopentadiene derivative **1** is converted in a Diels–Alder reaction with α-chloroacrylic acid chloride to the bicyclic compound **2**. Curtius rearrangement with subsequent hydrolysis gives the ketone **3**, which is converted to the lactone **4** in a Baeyer–Villiger oxidation. After saponification of the lactone, the acid is subjected to a resolution of the enantiomers with an optically active amine (e.g., amphetamine). Iodine lactonization of the acid **5** and benzoylation give the benzoate **6**. Reductive elimination of the iodine with tributyltin hydride and subsequent hydrogenolysis of the benzyl ether yield the Corey alcohol **7**. Oxidation to the aldehyde followed

Table 5. Uses of prostacyclins in human medicine

Structure	Generic name, CAS registry no.	Originator	Trade name or phase of development	(Potential) indication

hydride (DIBAH) and a subsequent Wittig reaction yield the acid **11**, which gives natural $PGF_{2\alpha}$ after cleavage of the protecting groups.

Synthesis of PGE_2 via the Cyclopentenone Method According to C. J. SIH (Fig. 4). As an example of this synthesis strategy, a method for the production of natural PGE_2 will be described [82]. Optical activity is introduced by a microbiological reaction. The triketone **13** can be obtained in several steps from the acetoacetic ester **12**. The chiral alcohol **14** is made by a regio- and enantioselective, microbiological reduction of the racemic triketone **13**. Conversion to an enol sulfonate, reduction, and protection of the hy-

Figure 3. Synthesis of $PGF_{2\alpha}$ according to E. J. COREY

droxyl group yield the cyclopentenone **15**. The stereospecific 1,4-addition of the cuprate **16** to the α,β-unsaturated ketone **15** and cleavage of the protecting groups give the methyl ester of PGE_2 **17**, which yields natural PGE_2 by microbiological saponification. Saponification with a base is not possible because of the labile β-hydroxyketone moiety.

Synthesis of PGE_2 via the Three-Component Method According to R. NOYORI [83] (Fig. 5). This is a "one-pot" process for the introduction of the α- and ω-chain. The optically active 3-hydroxycyclopentenone derivative **18** reacts with the organolithium compound **19** in a copper-catalyzed 1,4-addition. Then the resulting enolate reacts with the allyl iodide **20** via an organotin intermediate to give the PGE_2 derivative **21**. Cleavage of the protecting groups yields PGE_2.

Figure 4. Synthesis of PGE_2 via the cyclopentenone method according to C. J. SIH

Figure 5. Synthesis of PGE_2 via the three-component method according to R. NOYORI

Figure 6. Synthesis of prostacyclin (PGI_2) from $PGF_{2\alpha}$

Figure 7. Synthesis of TXA_2 according to W. C. STILL

Synthesis of PGI_2 from $PGF_{2\alpha}$ (Fig. 6). The synthesis of prostacyclin (PGI_2) from $PGF_{2\alpha}$ was described almost at the same time by five different teams independently of each other [84]. Esterification of natural $PGF_{2\alpha}$ with diazomethane and subsequent iodine lactonization yield the PGI_1 derivative **22**. Basic elimination with diazabicyclononene (**23**) gives the enol ether **24**, which, in turn, yields the sodium salt of PGI_2 after saponification. The free acid is normally not made because it is very unstable.

Synthesis of TXA_2 According to W. C. STILL [85] (Fig. 7). Starting with natural thromboxane B_2, a 1,15-macrolactone is synthesized as an intermediate with the help of the pyridine derivative **25**. Elimination of the 11-hydroxyl group with the Mukaiyama reagent **26** followed by a HOBr addition yields the bromohydrin **27**. An intramolecular Mitsunobu reaction gives the strained oxetane system **28**. Reductive elimination of the bromine with the help of polymer-bound tin hydride and subsequent saponification

Figure 8. Synthesis of LTB_4 according to E. J. COREY

furnish the sodium salt of TXA_2. It has not yet been possible to synthesize free TXA_2 because of its great instability.

Synthesis of LTB_4 According to E. J. COREY [86] (Fig. 8). The lactol **29** can be made from D-(+)-mannose in a few steps and is then converted to the olefin **30** in a Wittig reaction with subsequent tosylation. Methanolic HCl simultaneously cleaves the acetonide and the silyl ether. The vicinal hydroxyl groups in the resulting triol are converted to the carbonate with phenyl chloroformate. Nucleophilic substitution of the tosylate by the remaining secondary hydroxyl group yields the epoxide **31**. The epoxy aldehyde obtained after saponification and glycol cleavage with lead tetraacetate is converted to the triene **33** in a Wittig reaction with the phosphorane **32**. The epoxide opening with HBr proceeds with simultaneous displacement of the diene system. The resulting primary bromide is converted to the Wittig salt **34** with triphenylphosphine. Deprotonation with butyllithium and reaction of the resulting ylide with the aldehyde **35** give the protected LTB_4 derivative **36**. Stepwise saponification produces natural LTB_4. The aldehyde **35** is synthesized in several steps from the acetonide of the deoxyribose **37**.

Synthesis of LXA_4 According to J. ROKACH [94] (Fig. 9). The enantiomerically pure carbonate **38** can be made in five steps from commercially available 2-deoxy-D-ribose. Swern oxidation followed by a Wittig reaction and subsequent isomerization provides the diene aldehyde **39**. A second Wittig reaction with the known optically active ylide **40** yields the 1:1 E/Z-mixture **41**. Removal of the silyl group followed by E/Z separation and final saponification affords the desired lipoxin A_4.

1. Introduction

The term protective gas describes a gas that does not react with its environment (i.e., remains inert). This property is often utilized to protect materials from the ambient atmosphere, usually from the effects of oxygen. Protective gases are also used as carriers for reactive substances. Argon, nitrogen, or carbon dioxide can be used. Argon can be considered the best protective gas because it is completely inert and does not react with or form compounds with other elements. However, argon is considerably more expensive than nitrogen or carbon dioxide, and is therefore used only where materials could react with these gases or where the amounts of gas needed are so small that price is not a determining factor in the choice of protective gas.

Users of protective gases either produce them in gas generators or have them delivered by a manufacturer. Depending on the type of use, protective gases are supplied in high-pressure bottles on mobile pallets, in bundles, or for larger volume requirements, in liquid form via mobile tankers.

For very large consumption, nitrogen can be produced by membrane separation or pressure-swing absorption (PSA) plants installed in the user's factory and operated by the gas supplier. When the supplier delivers gases or operates the production plant, he assumes responsibility for quality, for matching supply to demand, and for the composition of the protective gas.

2. Protective Gases in Safety Technology

In safety technology, protective gases are used in containers, vessels, silos, or pipelines that contain flammable gases, liquids, or dusts, to lower the oxygen content of the atmosphere until it is below the explosion limits for the application in question, so that fires and explosions are prevented [1–3].

Explosive limits for various substances are listed in Tables 1 and 2.

Gaseous nitrogen or carbon dioxide is used, the choice depending on the type of application environment and the flammable material in question.

The type of inerting equipment used also depends on the character of the flammable material and the conditions of the gas space to be inerted.

A carbon dioxide inerting installation for silos is shown in Figure 1. Nitrogen is used in large quantities in mines for preventing and fighting underground fires. Here, liquid nitrogen is

n-Pentane	C_9H_{12}	1.43	8.0		476
Natural gas		5.0	15.0		645
Phenol	C_6H_5OH			+79	605
Propane	C_3H_8	2.1	9.5		470
Propene	C_3H_6	2.2	9.7		
Styrene	$C_4H_5CHCH_2$			+32	490
Toluene	$C_6H_3CH_3$	1.2	7.0	+ 6	535
Town gas and grid gas		6	36		560
Water gas	$CO+H_2+N_2$	7	70		ca. 540
o-Xylene	$C_6H_4(CH_3)_2$	1.0	7.6	+30	465

brought to the fire and evaporated in situ. If an inert gas is to be stored where it will be used in an emergency, the storage loss rates for different gases in various quantities must be taken into account:

1) Nitrogen can be stored without loss only if it is kept in cylinders or cylinder bundles
2) Carbon dioxide is the most suitable gas for large installations because it can be stored without loss even in large quantities due to the nature of CO_2 storage equipment

Nitrogen can be taken in gaseous form directly from the cylinders. However, the usage rate for gaseous carbon dioxide is restricted because it is present in the cylinder in liquid form, the rate of removal of the gas being limited by the pressure drop in the bottle during vaporization of the liquid. If the pressure falls below 5.18 bar (0.518 MPa), CO_2 can exist only in solid or gaseous form. If CO_2 is removed as the liquid phase to increase the rate, evaporation of liquid CO_2 produces dry ice (solid CO_2). The solid particles can generate static electricity and cause ignition of the flammable or explosive atmosphere. Therefore, only gaseous carbon dioxide should be used for inerting purposes.

If a protective gas is to be used continuously in large amounts (e.g., in pneumatic conveying equipment or for blanketing process plant), PSA or membrane plants can be used to lower the oxygen content of the ambient atmosphere to the required concentration.

Figure 1. Inerting with carbon dioxide [4]
a) Sprinkler; b) Control unit c) Metering unit; d) Silo

Inerting should be controlled by monitoring oxygen concentration to ensure that it is kept below the lower explosion limit.

Table 2. Limiting oxygen concentration for inerting various air – powder mixtures with nitrogen at ca. 20 °C and 0.1 MPa total pressure in a 1-m^3 vessel with an explosion energy of 10 kJ [2]

Type of dust	Mean particle size, µm	Limiting oxygen concentration, vol %
Aluminum	22	5
Barium stearate	< 63	13
Bisphenol A	34	9
Cadmium laurate	< 63	14
Cadmium stearate	< 63	12
Calcium stearate	< 63	12
Cellulose	22	9
Coal	17	14
Dibenzoyl peroxide	59	10
β-Naphthol	< 30	9
Herbicide	10	12
Maize starch	17	9
Methyl cellulose	70	10
Organic pigment	< 10	12
Paraformaldehyde	23	6
Pea flour	25	15
Polyacrylonitrile	26	11
Wood	27	10
Polyethylene (high density)	26	10
Rye flour	29	13
Soot	13	12
Synthetic resin	63	10
Wettable sulfur with 10 % lignosulfate	30	7
Wheat flour	60	11

The method of controlling the flow rate of protective gas varies with the particular application. Smoldering combustion in coal dust silos is best detected by continuously measuring the CO content in the free space at the top of the silo. Temperature monitoring is often used in this application, but the difficulty is to be sure that the measurement point is correctly located.

In mines, control is based on the determination of methane gas.

Inerting can be effected by various methods: mixing, displacement, and pressure change. In the last of these processes, a vessel can be pressurized with inert gas, the pressure then being reduced to atmospheric, or the vessel can be partially evacuated and then refilled with inert gas. The vessel must be capable of withstanding the applied pressures.

The process of inerting by the mixing and displacement methods depends on the type of gas space to be treated and the nature of the explosive atmosphere.

The displacement method requires the largest possible density difference between the gas to be displaced and the protective gas.

Investigations have shown that silos containing pulverized brown coal can be inerted with CO_2 added via fluidizing equipment. To displace oxygen from the charge, the free space should be inerted first [5].

According to TRD 413 (German regulation for pressurized vessels), explosive dust – air mixtures in brown coal silos are prevented if the oxygen concentration is < 12 vol %. Experiments have shown that this may be achieved by the addition of 2 kg of CO_2 per cubic meter of free space in the silo. When choosing an inert gas, the change in the limiting oxygen concentration with increasing temperature must be considered. Investigations with brown coal have shown that this limit is reduced by ca. 1.3 vol % per

100 °C temperature increase when inerting with nitrogen [6]. Carbon dioxide has been shown to be the more effective inerting gas because it gives a reduction in limiting oxygen concentration of only 0.5 vol % per 100 °C temperature increase.

Table 3. Use of protective gases in the food industry

Process	Gas used			
	N_2	CO_2	O_2	Mixture
Packaging				
Dairy products	+	+	–	N_2–CO_2
Fresh meat	–	–	–	N_2–CO_2–O_2
Sausage and meat products	–	–	–	N_2–CO_2
Fish and seafood	–	–	–	N_2–CO_2
Bakery products	–	+	–	N_2–CO_2
Farinaceous products (pasta)	–	–	–	N_2–CO_2
Vegetables	+	+	+	N_2–CO_2
Ready-to-serve meals	–	–	–	N_2–CO_2
Dried food	+	+	–	N_2–CO_2
Cold grinding (e.g., spices)	+	+	–	–
High-pressure extraction (e.g., coffee)	–	+	–	–
Controlled-atmosphere storage (e.g., fruit, cheese)	+	+	–	–
Silo storage (e.g., cereal, flour)	+	–	–	–
Inerting (e.g., storage tanks and pressure tanks)	+	+	–	–
Sparging (e.g., fruit juice)	+	–	–	–
Carbonated beverages (e.g., beer, sparkling wine)	–	+	–	–
Tapping/dispensing (e.g., beer)	+	+	–	N_2–CO_2

3. Protective Gases in Food Technology

Carbon dioxide, nitrogen, and in special cases, oxygen, or mixtures thereof, are used as protective gases in the preparation, packing, storage, and transport of solid and liquid foodstuffs (see Table 3). The gases inhibit or eliminate various changes that can take place in foods. These changes are:

1) Chemical (oxidation and discoloration)
2) Biological (enzymes already present or generated by microorganisms)
3) Microbial (bacteria, yeasts, molds)
4) Physical (changes in aroma, volume instability, moisture pickup)

These effects are very important in products of this type because their characteristic properties (fat content, aroma, color, and consistency) are very sensitive to oxidation [7–9].

The protective gases are odorless, tasteless, and not harmful to health, and need not be declared.

Carbon dioxide is soluble in water and fat, has bacteriostatic and fungistatic properties, and displaces oxygen. At low temperature and high pressure, it reacts readily with water to form H_2CO_3, which has bactericidal and antimicrobial activity due to its acidity. When moist products are packaged in an atmosphere of pure CO_2, a partial vacuum can be formed by combination of CO_2 with the water present [7], [10], [11].

Nitrogen is used to replace oxygen, and is chemically and biologically inert, although it does have some microbiological activity, mildly inhibiting the metabolism of aerobic bacteria.

Oxygen, mixed with nitrogen and CO_2, is used in the packaging of fresh meat to conserve oxymyoglobin. This is permitted by the German Meat Regulations (Appendix 1) and need not be declared.

Carbon dioxide and nitrogen are also used as cooling media in cryogenic chilling and freezing plants, maintaining an oxygen-free and virtually sterile atmosphere.

The two processes for packaging under a protective gas (Fig. 2) are

1) Flushing with gas in vertical or horizontal continuous-tube bagging machines
2) Replacement of atmospheric air in deep-drawing or chamber machines

In the gas-flushing process,the air in the packaging is replaced continuously by flushing with the protective gas, the gas consumption being

Figure 2. Processing for packaging under protective gas

three to five times the bag volume. The machine forms a tube of plastic film into which the gas is fed through a nozzle. The end of the gas nozzle is near the point at which the hot welding is carried out. A cushion-shaped package is formed.

In the air replacement system in chamber machines, the product is placed in a bag, evacuated in a chamber, refilled with the gas, and finally heat-sealed. In chamber machines, gas consumption is 0.5 times the package volume. Thermoforming machines for making semirigid boxes are provided with two rolls of plastic sheet. The lower, thermoplastic sheet is drawn to form a container in which the product is placed. The package is evacuated in the vacuum chamber; the gas is injected; and the package is hermetically sealed, the upper sheet forming a closed lid. Gas consumption is 0.2 – 0.4 times the package volume [11].

When large amounts of dissolved oxygen are present in the product (e.g., in granular products, products consisting of porous pieces, or fruit juices with a high fruit content), special equipment and processes are necessary: for example, injection equipment linked to the bagging machines, gas purging of filling nozzles, or sparging.

4. Protective Gases in Metallurgy and Smelting

4.1. Introduction of Gases through Permeable Elements in Metallurgical Vessels

Inert gases are blown into metal melts to produce a physical effect (degassing) or mechanical effects (agitation and purging).

Degassing. The partial pressure of the gases dissolved in the melt is reduced by blowing an inert gas into the melt. The dissolved gases diffuse into the rising bubbles of the sparging gas and are removed from the melt.

Purging. The inert gases rising through the melt cause flotation of nonmetallic inclusions such as oxide or slag particles. The bubbles are extremely small and adhere to the suspended particles, carrying them to the surface of the bath where they are removed as slag or dross.

Figure 3. Permeable stirring element in a vessel or furnace bottom

Agitation. Intensive and thorough mixing of the melt is required when metal treatment agents or alloying elements are added that must react with the melt, or to homogenize the temperature distribution and chemical composition of the melt.

Sparging aluminum melts with inert gases is used mainly to lower the hydrogen content, thereby decreasing the porosity of the casting.

When aluminum is melted in foundries in crucible furnaces it is sparged with argon or nitrogen introduced through permeable lances immersed in the melt. The sparging time is ca. 10 min, and 0.2 – 0.5 m^3 of inert gas is used per tonne of aluminum.

The spinning nozzle inert flotation (SNIF) refining process is used for sparging larger aluminum melts. After being melted in a smelting furnace, molten aluminum is transferred to the SNIF furnace where hydrogen and nonmetallic impurities are removed. The melt in the furnace is kept in motion by one or two rotating nozzles through which argon is injected, causing degassing. Argon consumption is ca. 0.4 m^3 per tonne of aluminum.

The SIGMA process is also used for sparging aluminum melts. Here, inert gases are introduced into the reactor through a bottom plate made of a permeable refractory material. A baffle plate in the reactor causes intensive mixing of the metal and the gas, and increases the dwell time of the aluminum [12].

If nitrogen is used, aluminum nitride can form, and argon is therefore preferred. The argon consumption is ca. 1.5 m^3 per tonne of aluminum. To remove lithium from aluminum melts, the sparging gas consists of a mixture of nitrogen or argon with 25 – 50 % sulfur hexafluoride as the reactive gas.

The degassing of steel melts is generally carried out under vacuum. The ladle is filled with molten steel and placed in a vacuum chamber. The inert gas is introduced through a permeable ceramic plate in the base of the ladle, and acts as both a sparging and an agitating gas.

Alternatively, a porous ceramic plug can be built into the floor of small induction furnaces (0.5 – 5 t), which are used to produce alloy and high-alloy casting steels. Stirring with an inert gas removes dissolved impurities, such as deoxidation products, from the steel melt [13]. Sparged steels show a considerable increase in linear extension and necking. The quantity of impurities detectable by micrography can be reduced by > 70 %, so that the weldability of these steels is improved considerably. The stirring time is 15 – 20 min with an argon consumption of 1 –1.5 m^3 per tonne of steel.

Porous plugs are also used in electric-arc steel melting furnaces [14]. Stirring of the melt leads to

1) Acceleration of the reaction between the metal and the slag
2) Homogenization of the temperature and chemical composition of the melt
3) Better heat transfer between the arc and the melt

The stirring elements (see Fig. 3) are usually built into the bottom of the electric-arc furnace. These are carbon – magnesite elements with several small steel tubes. The argon consumption is ca. 0.2 m^3 per tonne of steel. The sparging process leads to energy savings of 10 – 15 kW per tonne of steel and a reduction in the consumption of steel scrap of ca. 5 kg per tonne of steel. An improvement in purity also occurs [14].

In steelworks, both before and during pouring of the steel an inert gas is injected through permeable blocks in the bottom of the ladle to agitate the steel and homogenize the melt. Temperature homogenization is particularly important for the continuous casting process because temperature variations can lead to problems in pouring the melt and to tearing of the metal strand. In continuous casting plants, the tundish offers the last possible opportunity for removal of inclusions from the melt before it solidifies; gas injectors can also be built into the base of the tundish. Argon consumption is 0.05 – 0.2 m^3/t. Two injectors are used for each tundish (Fig. 4) [15].

Figure 4. Tundish with injectors
a) Ladle; b) Shroud; c) Tundish; d) Mold

In the production of nodular cast iron the melt can be agitated with a powerful jet of nitrogen that is used to mix in calcium carbide, which reacts with sulfur to form calcium sulfide, thereby desulfurizing the melt [16]. Agitation by a gas stream can also be used for carburizing, magnesium treatment, or inoculation, etc., which can be carried out consecutively in the same ladle. This process can also be used for continuous desulfurization in a cupola furnace. A permeable block is built into a treatment vessel located between the cupola and the holding furnace.

4.2. Protection of Molten Metals from the Ambient Atmosphere

When a melt is poured from one metallurgical vessel into another, a large amount of the metal's surface area comes in contact with the surrounding atmosphere. The metal stream absorbs considerable quantities of oxygen by chemical reaction, so the purity of the metal and its working properties are impaired. In the continuous casting of steel, contamination of the molten metal is prevented by fitting a shroud, swept by inert gas, between the tundish and the mold. Another system consists of a movable shielding device fitted underneath the tundish, surrounding the metal stream for almost its entire length. A stream of inert gas flows between the device and the metal stream. The metal stream between the ladle and the tundish can be protected by two methods: a ceramic shroud filled with inert gas or a hood. Shrouding the pouring operation prevents oxidation of the metal stream in each case. Some steelworks prevent oxidation during pouring by providing the tundish with a cover. The free space between tundish and cover is filled with argon, enabling the metal to be poured into the tundish in a neutral atmosphere. If some degree of nitriding is acceptable, nitrogen can be used as the protective gas.

Purging of vessels to remove air before filling with metal can also be carried out by using a liquefied inert gas. The liquefied gas settles at the bottom of the vessel where it vaporizes and displaces the air in the vessel. Vaporization proceeds relatively slowly, due to the formation of a gas film between the hot refractory material and the liquefied gas, which acts as an insulating layer to prevent rapid vaporization of the liquefied gas. The metal is then poured into the vessel filled with inert gas. In steel foundries, induction furnaces for the production of alloy and high-alloy steels are inerted with a blanket of liquefied argon during melting [17], [18]. Liquefied argon vaporizes on contact with the hot metal, producing a protective gas atmosphere that blankets the hot metal and prevents oxidation.

In powder metallurgy, liquid metals are powdered by atomization with argon or nitrogen. The use of inert gases ensures that the metal surface is not oxidized. This is not the case when water is used.

Minimization of oxidation can also be used to reduce dust emission. Procedures aimed at reducing smoke generation are being tested in blast furnaces [18]. So-called brown smoke, mainly vaporized iron oxide, is produced when a large surface of molten iron is exposed to oxidation by atmospheric oxygen during teeming or at the pig iron spout. In these cases, oxidation can be prevented by a blanket of inert gas (carbon dioxide or nitrogen). Carbon dioxide is added to the molten iron in the form of dry ice. Due to its higher density, dry ice resists the buoyancy of the hot gases better than nitrogen, comes in closer contact with the metal surface, and isolates it from the ambient atmosphere. Furthermore, nitrogen can lead to nitride formation in the pig iron, which can impair the quality of the steel. The route of the raw iron from the tapping hole to the filling point of the transport container must be enclosed by a cover that is as leakproof as possible [19]. When protective gases are used to reduce smoke production, the dedusting equipment can be of smaller dimensions or can be eliminated entirely, with corresponding reductions in the cost of disposing of the metal oxide dust.

If air is allowed free access to molten iron or steel, nitrogenization of the metal can occur due to reaction with atmospheric nitrogen. For certain grades of steel, the nitrogen content must be kept low to prevent impairment of steel quality. The largest exposure of the metal surface to the atmosphere occurs during teeming or on tapping of the converter or electric-arc furnace into the transporting ladle. The metal stream can be protected by using CO_2 snow, which is produced by special snow-generating equipment [20].

4.3. Use of Protective Gases in the Converter

In steel production, molten pig iron is refined by removing carbon by treatment with ca. 50 – 60 m^3 of oxygen per tonne of iron. The oxygen must be evenly distributed in the melt with a high mixing energy. Injectors or bottom blowers can be located in the floor of the converter. Nitrogen or argon passes through these and causes vigorous mixing of the melt (Fig. 5), homogenizing its temperature and chemical composition. Inert gas consumption is 1 – 3 m^3 per tonne of steel. After this treatment, the melt is tapped into a pouring ladle, where metallurgical treatment is carried out. Here, inert gases are also used as carriers for the addition of alloying materials via a blowing lance, or for mixing and homogenizing the steel melt by sparging. Large quantities of inert gas are used in the production of stainless and heat-resistant steels in the argon – oxygen decarburization (AOD), Klöckner combined blowing (KCB), and metal refining process lance (MRP-L) methods. Inert gases (argon and nitrogen) are mixed with the blowing oxygen to lower the partial pressure of carbon monoxide. The resulting thermodynamic conditions promote the oxidation of carbon in preference to oxidation of chromium [21]. The amounts of argon depend on the types of steel produced (15 – 25 m^3 per tonne of steel).

Figure 5. Bottom blown quick basic oxygen process (Q-BOP) converter

4.4. Use of Protective Gases in Heat Treatment of Metallic Components

Heat treatment is used to modify the properties of solid metallic components by changes in temperature and by the action of the ambient atmosphere.

Table 4. Protective gases for heat treatment of metals [22] *

Material	Breaking vacuum	Bright annealing	Decarburizing annealing	Carbon-neutral annealing	Carburizing	Nitriding	Carbonitriding	Sintering	Tempering	Brazing	Conversion of residual austenite
Steel $<0.3\,\%$ C		N_2 N_2+H_2 N_2+HC	N_2+H_2 $(+H_2O)$	N_2 N_2+HC	N_2+HC $(+O_2)$	N_2+NH_3	N_2+HC $+NH_3$	N_2 N_2+H_2		N_2 N_2+H_2

Noble metals	N_2 Ar	N_2 N_2+H_2								N_2 N_2+H_2	

* HC = hydrocarbon.

The protective gas atmosphere not only protects metallic products from oxidation (heat treatment, sintering, hardening), but also changes the chemical composition of the surfaces by diffusion (e.g., of nitrogen and carbon in nitriding, carbonitriding, and carburizing processes). To achieve this, the carrier gas (nitrogen) is mixed with hydrocarbons and ammonia. Moisture and oxygen from the components being treated and from leaks in the heat treatment furnace enter the furnace atmosphere. The resulting change in the composition of the furnace atmosphere could lead to oxidation of the components. Therefore, a proportion of the protective gas atmosphere must have a reducing effect. This is achieved by adding hydrogen. Various gases are used in protective gas atmospheres, depending on the desired properties of the components (see Table 4).

Protective gases and carrier gases produced from hydrocarbon – air mixtures in generators, or from ammonia in ammonia crackers, are increasingly being replaced by protective gases from gas suppliers.

The protective gas atmosphere is mixed by the user to give the desired composition and introduced into the heat treatment furnace. Substitutes for some generator gases can be produced by catalytic reaction of a fuel gas – air mixture and mixing with nitrogen either inside or outside the heat treatment furnace to form a protective gas atmosphere.

5. Protective Gases for Gas-Shielded Arc Welding Processes

All gas-shielded welding processes have one aspect in common: they require a shielding gas to protect the molten welding pool from the atmosphere. Various welding processes utilize inert, oxidizing, reducing, and quasi-inert protective gases, or mixtures of these, depending on the process and the metal being welded (Table 5) [23]. Optimized mixtures of protective gases offer additional advantages and often improve both quality and productivity [24]. Some welding processes do not allow the use of active protective gases, for example, the tungsten – inert gas welding process (TIG), plasma arc welding (PAW), and the infrequently used tungsten – hydrogen welding process (THG), because an active component (CO_2, O_2) would lead to melting and corrosion of the arc-producing electrodes, and inclusions of tungsten and thorium in the weld. In processes involving the melting of wire electrodes [subdivided into metal – inert gas (MIG) and metal–active gas (MAG) processes, depending on the protective gas used] the choice of gas depends mainly on the material to be welded [23]. Various protective gases, inert or active, may be used for the same material in some cases. However, the selection of a suitable or particularly advantageous protective gas requires a knowledge of the effects of individual gases on the welding process. These effects are principally a function of the physical properties of the gas.

Table 5. Purity, dew point, and reactive behavior of protective gases (DIN 32 526)

Gas	Purity, vol % (min.)	Dew point at 1 bar, °C (max.)	Chemical behavior on welding
Argon	99.99	−50	inert
Helium	99.99	−50	inert
Carbon dioxide	99.7	−35	oxidizing
Oxygen	99.5	−35	oxidizing
Nitrogen	99.5	−50	unreactive
Hydrogen	99.5	−50	reducing ∗

∗ Protective gas mixtures with > 10 % H_2 are an explosion hazard and should be flared off.

The welding processes mentioned are not described in detail here; further information can be found in [25–27] (see also → Welding and Cutting).

The gases are most usefully characterized by the following physical properties (see Table 6 and Fig. 6): gas density, thermal conductivity, and ionization energy.

These properties are often temperature dependent. The important temperature range for gas-shielded arc welding lies between ca. 2000 and 8000 °C. Only the plasma arc welding process involves higher temperatures [28].

Gas density has a direct influence on the quantity of gas required for effective protection. A dense protective gas provides better protection than a lighter gas at a given flow rate.

High thermal conductivity has a beneficial effect on the shape of the bead and on the metal in the weld pool as well as in the heat flow zone. The arc column becomes larger, and the bead formed is therefore wider and has good surface

Table 6. Some physical properties of protective gases [28], [29]

Figure 6. Thermal conductivity of various protective gases [28]

properties [24, p. 152]. However, the thermal conductivity does not vary linearly with temperature, being the result of individual contributions determined by dissociation – ionization processes [30].

The ionization energy of a gas is very important for the electric arc. If only a small amount of energy is required to ionize a gas (i.e., to make it conduct, see Table 6), the arc is easier to strike.

Apart from these important gas properties, the relationship between the electrical conductivity of a plasma and the resistance and voltage of the arc is also significant [28].

Exploitation of these physical properties in welding processes leads to the following application for the various protective gases:

Argon has very favorable physical properties, is produced economically in air separation plants, and is the most widely used protective gas in welding technology. It is odorless, tasteless, and colorless; is available with a purity of 99.996 vol % (4.6 quality); and is used in the welding of high-alloy Cr – Ni steels and Al-, Cu-, and Ni-base alloys by the TIG and PAW welding processes, and also for MIG welding of metals suitable for this process.

Argon is the base gas for the MAG welding of high-alloy Cr – Ni steels, and is also very suitable for unalloyed and low-alloy steels [28]. It has a relatively high density, giving a stable covering of protective gas, and is therefore used in TIG welding of materials that are sensitive to oxygen or nitrogen, such as titanium,

Table 7. Standardized gases and gas mixtures for gas-shielded arc welding [33]

Process	Materials	Gas designation		Composition or purity, wt %	DIN 32526
		AL international	Germany		
MAG (metal–active gas welding)	all unalloyed and low-alloy steels (e.g., structural steels, fine-grained structural steels, tube steels, shipbuilding steels, heat-resistant steels)		Kohlendioxid	CO_2 99.95%	C 1

tantalum, and niobium. Very high-purity argon (99.998 vol %, or 4.8 quality) is recommended for this application because the metals have a high affinity for N_2 and O_2. Gas suppliers also add other gaseous components (see Table 7), of-fering the user standardized two- or three-component gas mixtures that ensure problem-free, cost-effective welding.

Helium has for a long time played only a minor role in welding technology because of its high cost. However, helium is now being used in increasing quantities in certain welding applications where its high price is compensated by its special physical properties. Mixtures of 30 – 50 % helium with argon are used for welding materials of high thermal conductivity (e.g., Al, Cu, and their alloys) by the TIG, MIG, and PAW processes. Because of helium's high thermal conductivity, the need to preheat the workpieces, especially those of heavy section, is reduced and sometimes completely eliminated. This property also produces a larger, hotter fusion zone, which means that more time is available for degassing, and porosity is therefore considerably reduced. The high ionization energy of helium causes problems in striking the arc, but also leads to a high energy of recombination, which is largely returned to the welding pool. This results in deeper penetration and increased welding speed and deposition rate. Helium is also used in the MAG welding process. Addition of 50 % helium to the standard mixture of 2 % CO_2 in argon has been found to be suitable for high-alloy Cr – Ni steels, and addition of 5 % to the standard mixture of argon with 18 % CO_2 is used in flux- cored wire welding of unalloyed mild steels [28], [31]. Pure helium is used in automated TIG welding of aluminum, copper, and nickel components, particularly if preheating cannot be carried out. Since the density of helium or helium-rich mixtures is lower than that of argon, higher gas flow rates are required.

Oxygen is used as a minor oxidizing additive to argon mixtures to improve welding by the MAG process. It leads to the formation of metallic oxides, which lower the surface tension of the molten weld pool. Smaller droplets of weld metal are produced that become detached quickly and smoothly, leading to reduced spattering. In practice, a 1 – 3 % oxygen content for welding Cr – Ni steels is suitable, or 8 % oxygen in argon for welding structural steel [32].

Carbon dioxide has a high density, good thermal conductivity, and energy of recombination originating from the dissociation reaction that takes place in the electric arc ($CO_2 \rightleftharpoons CO + O$). Hence, it is the most important oxidizing component of mixtures for the MAG process for unalloyed and low-alloy steels, as well as for high-alloy Cr – Ni steels. Some standard mixtures are listed in Table 7.

Hydrogen is colorless, odorless, nontoxic, and flammable. It has favorable physical properties (e.g., high enthalpy, high thermal conductivity) and a high energy of recombination, leading to its use in the TIG and PAW welding processes. For welding high-alloy Cr – Ni steels, nickel, and nickel alloys, 5 % H_2 is added to argon. Hydrogen is also used as a back shielding gas. As a rule, ca. 10 % hydrogen is added to nitrogen. The reducing action of the hydrogen protects the root zone of welds (mainly on Cr – Ni steels) from undesirable oxidation.

Nitrogen is the main component of back shielding gas. Due to its very low chemical reactivity little danger exists of nitride formation in the relatively cool interior of the root zone. It is not used as a protective gas component in the welding processes considered here.

1. Introduction

Different values for the average daily requirement of food protein can be found in the literature. Values between 18 and 28 g per 1000 kcal of food intake should be appropriate. The lower the uptake of food energy, the higher must be the percentage of protein in food [1]. Between 1987 and 1989, 70.4 g of edible protein was statistically available daily *per capita* of the world population. About 65 % of these proteins were plant proteins [1961 – 1963: 62.2 g (68 %), 1969 – 1971: 64.4 g (66 %), 1978 – 1981: 67.5 g (66 %)] [2]. Thus, in spite of the rapidly increasing world population, the global supply of proteins has improved rather than deteriorated.

Until 1990, this also applied to the entire nutritional situation. A daily nutrient intake of 2600 kcal per person, which was judged to be adequate and was strived for, was achieved at the end of the 1980s even by China and the densely populated countries of Southeast Asia. Thus, more than half the population of developing countries is now considered to be adequately supplied. At the same time, however, the situation in some countries, especially in sub-Saharan Africa, has substantially deteriorated. In 1990, 220 million people in the poorest countries lived on less than 2000 kcal per day per person. The index for food production *per capita* in 1991 was 119.22 for Asia and 93.55 for Africa and, in comparison, 104.94 for Europe (basis: 1979 – 1981 = 100) [3]. On the other hand, the index for *total food production* in 1990 was 143.68 for Asia, a substantial 125.83 for Africa, and 108.22 for Europe. In other words, in contrast to Asia, the population growth in Africa is increasing faster than food production [4].

Because of the collapse of the former USSR and in the wake of wars, the global nutritional situation clearly deteriorated at the start of the 1990s. In September 1992, the FAO estimated the number of children on protein-deficient nutrition at 116 million.

By applying these statistics, differences in the biological value of individual food proteins do not come into play and a considerable portion of mostly plant proteins is assessed incorrectly. These are primary products used as fodder to obtain higher-quality animal proteins. If the feeding of grain and oilseeds is taken into account, only about 55 % of the originally produced food proteins are available for human nutrition. This proportion has a downward ten-dency (i.e., the increase in plant protein production benefits, in particular, the enhancement of animal proteins in developed countries).

An improvement in the protein supply of those in need could be expected primarily from increasing the cultivation of protein-rich leguminous plants and types of grain in needy countries. This can be achieved by releasing high-grade food proteins by the provision of inexpensive protein for animal feed, and from the development of low- cost plant protein concentrates that are of a high quality from a nutritional, physiological, and functional viewpoint. A gentler approach to natural resources is also required. Until 1989, for instance, worldwide fishing increased continuously to 99.5×10^6 t/a, but since then it has decreased rapidly due to overfishing (1990: 95.5×10^6 t). About 30 % of the fish caught are still processed into feed.

In the past, the development of *unconventional sources of protein* has not been as successful as expected. The marketing of new developments appears to be directed much more at replacing conventional protein sources in regions with high purchasing power than at reaching the needy classes of the world population. The largest financial scope for the cost of improvements exists in the case of expensive egg proteins, followed by meat and fish, while milk protein is by far the cheapest animal protein. However, since the functional imitation of milk protein is relatively easy and cost effective because of a lack of texture and sensory properties, strong competition exists to replace milk proteins.

Milk production represents the largest production reserves for nutritionally and physiolog-

ically valuable animal protein. About 60 % of the agriculturally utilizable land can be optimally cultivated as grassland. The conversion of irradiated solar energy via grassland → ruminants → milk, with meat as a side product, is much more efficient than any other path to animal protein. In fattening animals, however, considerably more high-quality protein is regularly fed to animals than recovered from them. The biological potential of the oceans to produce high-grade food protein is globally limited and, unlike exploitation of the land, can hardly be increased any further.

The *cultivation of grain* represents the most important global source of food protein. Whether cereals can in the long term play this role will depend on whether fossil energy – required for the production of inexpensive commercial fertilizers – is available for intensive cultivation to the same extent as before. Looked at from this standpoint, the cultivation of *leguminous plants* that do not require nitrogen fertilizer should be of steadily increasing importance. The largest increase in production is found in the case of soy protein. Until now, only about one-tenth of the harvest was employed directly for human nutrition, the remainder was used as feed. For climatic reasons, the cultivation of soybeans is restricted to a few regions of the earth. A search is still on for leguminous plants (e.g., lupines) that can improve the protein supply especially in needy regions.

In publications of the United Nations's Protein Advisory Group (PAG) (FAO/WHO/UNICEF/UNIDO), the main opinion is that the protein problem in undersupplied regions can be most effectively solved in the short term by the production of leguminous plants that thrive locally. These are then used to increase the value of the diet, which is normally rich in carbohydrate but low in protein – especially essential amino acids (particularly lysine and methionine) [5]. The development of protein-rich, lysine-enriched types of grain for suitable climates associated with the "green revolution" greatly contributed to the improvement in the world nutritional situation in the 1980s. With the help of genetic engineering, plants that are especially resistant to pests and agrochemicals should be developed in order to reduce harvest losses.

To what extent industrially produced *single-cell proteins* (yeast, bacteria, → Single Cell Proteins ; → Yeast), *algae,* and *leaf proteins* will gain importance for the human protein supply will depend, among other factors, on how strongly increases in the price of fossil energy and nonregenerable raw materials will affect production costs. The energy crisis of the 1980s had a very negative influence on developments. Moreover, the products should be absolutely harmless – they should contain no carcinogenic hydrocarbons and few nucleic acids and should be easily digestible. They should also be designed to possess attractive functional properties. If industrially produced proteins are used for animal food, they must compete with the cheapest protein carriers. Under these circumstances, predictions made about the future of industrial protein production seem daring, although these processes are extremely interesting from a process engineering point of view. Locally, the industrial production of single- cell proteins could become economically interesting if it can be coupled with measures for environmental protection and waste removal.

Table 1 presents a global survey of the protein supply. The figures were calculated on the basis of FAO statistics on average protein concentrations, without taking differences in quality into account [2, 3]. To compensate for fluctuations in annual harvests, the average of three-year production periods was used.

2. Plant Protein Products

2.1. Seed Protein Products

2.1.1. Cereal Protein Products (see also → Cereals and Cereal Products)

Cereal Producing Countries. The principal countries in which the most important types of cereals are grown are listed in Table 2, which also gives the annual production of each crop. As can be seen from Table 2, wheat, rice, and maize account for more than 80 % of the grain produced in the world.

Main Nutrient Content and Protein Nutritional Value of Cereals. Cereals are a source of both protein and starch (see Table 3). The protein content is ca. 10 wt %. The protein nutritional

[b] Grams of essential amino acids per gram of total nitrogen (egg protein: 3.2).
[c] PER (protein efficiency ratio).

value is in the range of average to good, the first limiting amino acid being lysine [*6899-05-4*] (see → Amino Acids, Chap. 5.1.). Therefore, mixtures of grain proteins with a protein having a high lysine content increase the protein nutritional value.

Isolation and Use of Maize and Wheat Proteins. The isolation of maize and wheat proteins is coupled primarily to the production of starch (→ Starch). In 1988, 70 % of the starch produced was obtained from maize and 5 % from wheat. The resulting *maize gluten meal* [*8002-80-0*] (obtained by wet grinding) has a protein content of 60 to 70 % and is used primarily in the feed industry (see Fig. 1). Only smaller amounts are employed in the production of protein hydrolysates and glutamic acid.

Zein (maize prolamine) [*9010-66-6*] is extracted from maize gluten by treatment with an aqueous solution of 88 vol % isopropanol and 0.25 wt % sodium hydroxide at 60 °C, and subsequent precipitation at −15 °C. Zein (producer: Freeman Industries, United States) is used as a surface coating for nuts, candies, tablets, and textile fibers.

Maize Germ Meal. In the isolation of maize germ meal, the maize germ is obtained by wet grinding. Most of the oil is then removed by pressing at 120 °C. The process is concluded by extraction of the remaining oil with hexane.

In the meantime, the separation of maize germ by dry grinding has also proved useful (e.g., Lauhoff Grain, Illinois Cereal Mills, Archer Daniels Midland, United States). In this case, the oil is extracted only with hexane.

The maize germ meals obtained after drying can be used directly for the processing of food or, in principle, as a raw material in the production of protein concentrates. The composition of these meals is given in Table 4.

A *protein concentrate* (i.e., a protein-enriched product obtained by concentration of the proteins in a protein-containing raw material) has been successfully prepared from deoiled maize germ (dry grinding) by *extracting* the protein with a mixture of aqueous solutions of 70 vol % ethanol and 0.7 wt % sodium hydrox-ide (11 : 1) (protein content ca. 60 wt %). The proteins of maize germ are very soluble in water: 20 % at the isoelectric point (≈ 5). The emulsion activity and emulsion stability amount to approximately 50 % (ca. 10 % at the isoelectric point). The fat absorption of maize germ proteins is considerable, being 549 mL of oil per gram of protein. Therefore, maize germ meal and the corresponding protein concentrate are employed in the making of bread and other baked goods, meat products (sausages), and sauces. Textured maize germ meal can be produced by extrusion. It is ideally suitable for use in ground-meat-like products.

The protein enrichment of wheat meal *by air classification* is not very common because the energy required for pin-mill grinding is high. However, factories employing this process do exist in the United States, France, and Germany. The protein content of the wheat meal (at least 20 %) is increased to 25 % by means of air classification. Meal of this type is used primarily to prepare bread flour. It improves both the dough making and baking process as well as the quality of the bread.

Vital Gluten. The vital gluten obtained on separating starch and gluten is often considered the primary product in wheat-starch production. In such cases, instead of whole grain, wheat meal is used as the starting material because it allows an especially good separation of gluten. The separation of wheat vital gluten is shown in Figure 2. The starch is washed out of the wheat dough in two steps (Martin process); the resulting wet vital gluten contains about 11.5 wt % protein, 2 wt % starch, and 0.9 wt % fat. Since the beginning of the 1980s, the soluble wheat albumins and globulins have been isolated from the wash water by heat coagulation, according to the Raiso process (Finland). The resulting product is a protein-enriched flour.

Gluten is a protein complex whose minimum solubility in water is 20 – 30 wt % between pH 6.5 and 9.0. The solubility is increased to about 80 wt % in the acidic or alkaline pH range. To increase the solubility in the isoelectric range, wheat gluten is partially modified by enzymatic hydrolysis. In this way, proteins that have good emulsifying and foam producing properties are formed. The water absorption capacity of vital gluten is remarkable; it can absorb water up to 65 % of its mass. The wet vital gluten thus formed has pronounced viscoelastic properties and forms a firm gel when heated to 85 °C.

These functional properties explain the fact that at present, ca. 80 % of the wheat vital gluten

Figure 1. Isolation of maize gluten meal and maize germ meal and of the corresponding protein concentrates

After oil extraction with hexane (60 °C)	29	1	
Maize germ, dry grinding			
Without oil extraction	14	20	2.6
After oil extraction with hexane (60 °C)	17	1	2.3

∗ Protein efficiency ratio.

Figure 2. Isolation of protein-enriched flour and protein concentrates from wheat

produced is used in making bread and baked products. It is employed primarily in special breads and breakfast cereals. In the meat and sausage industry, vital gluten has proved useful as a binding agent for sausages and ground-meat products and in the production of sauces. By extrusion of vital gluten, excellent meat extenders can be obtained, which can partially replace the meat in ground-meat products. Gel-like meat analogues made from vital gluten are common in Japan.

As a result of its high biological value compared to gluten, *heat- coagulated* wheat protein is used primarily to improve the value of protein. The composition of wheat protein products is given in Table 5.

Producers and Trade Names of Wheat Gluten. Important producers of wheat gluten and a selection of the trade names of their products are listed below:

Ajinomoto, Japan	A-Glu
Allied Mills Industries, Australia	
Amylum, Belgium	Biogluten (vital gluten) SWP (sodium salt of a soluble wheat protein isolate)
Archer Daniels Midland, United States	Do-Pep Vital
Beldum, Belgium	
Cerestar, France	
Crespel & Deiters, Germany	
Dutch Protein and Services, Netherlands	
G.M.F.F., Minoteries à Féves, France	Fabaten (mixture of gluten and faba bean flour)
George Weston Foods, Australia	
Manildra Milling Corporation, United States	
Molinos Juan Semino, Argentina	
Nidefo, Netherlands	HPF 50 HPM (enzymatically modified vital gluten)
Nisshin Mill	Sun Meat (textured gluten, meatlike, protein content: 28 %)
Raision Tehtaat, Finland	
Roquette, France	Viten (vital gluten) Deviten (denatured)
Rovita, Germany	Rovita
Shiuslim, Japan	Hi Pro-P
Tenstar Aquitaine, France	
Tenstar Products, United Kingdom	
Wheat Industries, Iceland	

2.1.2. Oilseed Protein Products

Oilseed Producing Countries. Details about the annual production of important oilseeds and the main oilseed producing countries in 1989 are given in Table 6. Information on lupine is not available. Oilseeds represent important sources of protein with a high biological value, the most significant being soybean.

Table 6. Production (in 1000 t) and principal oilseed producing countries 1989 [22]

Oil plant	Production	Countries
Soybean	107 350	USA, Brazil, China, Argentina
Cotton	30 703	China, Former USSR, USA, Pakistan, India, Brazil
Peanut	22 594	India, China, USA
Rapeseed	22 302	China, India, Canada, France, Germany, Poland
Sunflower	21 867	Former USSR, Argentina, France, Turkey, Romania, China, USA
Sesame	2352	India, China, Sudan, Myanmar
Linseed	2121	Canada, Argentina, India, Former USSR, China
Castor bean	1155	India, China, Brazil
Safflower	908	India, USA, Mexico, Ethiopia

Main Nutrient Content and Protein Nutritional Value of Oilseeds. Table 7 shows that oilseeds are an equally good source of both protein and oil. The biological value of the proteins indicates that they are generally high grade. This applies particularly to soybean proteins [*9010-10-0*].

Isolation and Use of Soybean Protein Products [30]. *Soybean Flour. Whole-fat flour* is obtained by heat-treating soybeans in a moist atmosphere and subsequently shelling and grinding them. To produce *defatted flour,* steam-treated shelled beans are ground coarsely. The water content is then adjusted to ca. 10 wt % by tempering to enable the subsequent extraction of soybean oil [*8001-22-7*] with hexane, for example. Depending on the destruction degree of antinutritive factors, the extracted cake is then subjected to further heat treatment (toasting) and subsequently ground. Flour with a distinct fat and lecithin content is made by the addition of oil or lecithin to defatted flour (Table 8).

Table 5. Composition of differently isolated wheat protein concentrates [17–21]

	Protein-enriched flour (air classification)	Vital gluten	Enzymatically modified vital gluten	Soluble wheat protein	Heat-coagulated wheat protein (albumins + globulins)
Protein, wt %	25	80 – 85	85 – 90	85	40
Fat, wt %		0.5 – 2	0.5 – 2	8	
Carbohydrate, wt %		3 – 5	3 – 5	1	
PER (NPU) ∗	1.5 (64)	0.7 – 1.0 (58)			2.2

∗ Protein efficiency ratio (net protein utilization).

Table 7. Approximate nutrient content and biological value (BV) of oilseed proteins

Oilseeds	Protein content		BV [29]	Fat, wt %
	Original, wt %	Shelled defatted, wt %		
Soybean [28]	38	40 – 52	60 – 75	17 – 23
Cotton [28]	20	33 – 50	55 – 57	20 – 50

Saccharose		7		
Stachyose		6		
Raffinose		1		
Starch		≈ 15		

The functional properties of soybean flour can be determined to a considerable extent by the heat treatment process. For instance, flour of varying solubility, with protein solubilities between 10 and 90 wt % in water can be produced. Defatted types of flour, with and without added lecithin, have gained acceptance in the market. Lecithin- containing flour is used in the making of bread and baked products, mayonnaise, dressings, and sauces. Soybean flour without lecithin is employed primarily in the production of meat products, bread, and baked goods. Soybean flour can also be textured for use as a partial meat substitute (e.g., by extrusion).

Soybean protein concentrates commonly have a minimum protein content for the dry products of 60 – 65 wt % (determined as nitrogen content, N×6.25).

Soybean protein concentrates can be isolated to obtain the protein concentrates II, III, and IV as shown in Figure 3. The composition of these concentrates is listed in Table 9.

Table 9. Composition and properties of differently produced soybean concentrates [31]

Composition and properties	Extraction of soluble components with		
	Water (concentrate II)	Ethanol (concentrate III)	Acid (concentrate IV)
Water, wt %	3	7	5
Protein, wt %	70	66	67
Fat, wt %	1	0.3	0.3
Raw fiber, wt %	4	4	3
Ash, wt %	4	6	5
pH	6.9	6.9	6.6
Protein solubility, %	3	5	70

Generally, these products exhibit low water solubility but have good water- (3.5 g/g) and fat-binding (2.5 g/g) properties. They are used primarily in the production of meat products

Table 10. Composition of soybean protein isolates [31]

Protein, wt %	Water, wt %	Raw fiber, wt %	Ash, wt %	pH (aqueous solution)
88 – 95	5 – 10	0.1 – 0.2	1.2 – 2.5	4.6 – 5
85 – 93	5 – 8.5	0.2	3 – 7.5	6.9 – 7.2

Figure 3. Isolation of protein concentrates and isolates

(sausages to be heated or cooked), pasta, and bread, and baked goods.

In a cooking extruder, concentrates of this type can be textured in a heat – pressure process to give extrusion products. The same result can be achieved with the corresponding raw material flour. A fibrous microstructure is obtained in this process. With soybean protein concentrates, extrusion reduces the water solubility by two-thirds. The protein nutritional value, as expressed by the protein efficiency ratio (PER), is also reduced (from ≈ 2.4 to 2.1). Extrudates of this type are especially suitable for partial meat substitution. Soybean protein concentrates with high solubility, gelling, and emulsion stability can now be prepared by the gentle processing of soybeans.

Isolates of soybean proteins (glycinin [*9007-93-6*], conglycinin [*104042-07-1*]) are made from shelled soybeans according to the procedure shown in Figure 3. Their composition is given in Table 10. They are relatively soluble and exhibit good swelling (10 – 20 mL water/g), gelling, emulsifying, water-binding (≈ 400 wt %), fat-binding (≈ 150 wt %), and foaming properties (250 % increase in volume). Soybean protein isolates produce foams with a high stability. These isolates are used in the production of nearly all groups of food, especially meat products, pasta, bread, and baked goods, milk products, nonalcoholic beverages, and baby food. They are also employed in the making of new foods (spinning of fibers, texturization, and simulation), which include meat (on the basis of protein fibers) and milk products. The protein values of these products are given in Table 11.

No official information is available on the production volume of these products. The total production of soybean protein concentrate and isolate is estimated to amount to ca. 130 000 t and 80 000 t, respectively. A substantial portion of protein isolates is used in the paper industry and in the production of baby food. In the meat industry (e.g., in Europe, Japan, and the Republic of South Africa), soybean protein isolates and concentrates are used in the production of frankfurter-type sausages. In addition, about 30 000 t of soybean protein concentrate is used in the United States for ground-meat products for school lunches and for the army.

2.1.3. Legume Protein Products

Legume-Growing Countries. The legume-growing countries and their production volumes are listed in Table 13. As can be seen from Table 12, the *Phaseolus* bean and the pea have the highest production volumes.

Table 13. Production (in 1000 t) and principal legume (dry) producing countries, 1989 [33]

Plant	Production	Countries
Peas	16 447	Former USSR, France, China, India
		Hungary, UK

		Morocco, Germany, France,
		Italy
Lentils	2242	India, Turkey, Bangladesh,
		China
Total	57 985	

Main Nutrient Content and Protein Nutritional Value of Legumes. As shown in Table 14, legumes are sources of both protein and starch. Except for the proteins of lentils, which have a lower biological value, the other legume proteins (vicilin and legumin [*102426-92-6*]) have an average biological value. This is due to their relatively low content of sulfur- containing

Table 14. Approximate nutrient content and biological value (BV) of proteins of legumes

amino acids. However, since lysine concentrations are high, biologically high-grade products are obtained by mixing grain proteins with leguminous proteins.

Isolation and Uses of Legume Protein Products [40–48].

Faba Bean, Pea, and Chick-Pea Flour. Faba beans, peas, or chick-peas are subjected to heat treatment in a moist atmosphere, shelled, and then ground to obtain flour I (see Fig. 4). Antinutritive components are partially eliminated by aqueous extraction at pH 4.2 to obtain flour II. In contrast to soybean flour, protein concentrates cannot be isolated by aqueous extraction (i.e., the protein content of the flour does not increase).

The composition of these types of faba bean flour is given in Table 15; their functional properties are listed in Table 16. These properties are determined primarily by the main components globulins and starch and also by the highly functional phosphatides. Flour made from faba beans, peas, or chick-peas can be used for the same applications as soybean flour, and the high proportion of starch can be an advantage over soybean flour in these applications.

Faba Bean and Pea Protein Concentrates. According to Figure 4, faba bean and pea flour can be enriched in protein by air classification to yield protein concentrates. The composition and functional properties are given in Tables 15 and 16 for faba beans. The simultaneous enrichment of antinutritive components is a disadvantage of this process. Since the starch content of faba bean protein concentrate amounts to only 1 wt %, the fields of application for protein concentrates from faba bean and soybean are identical.

Faba Bean and Pea Protein Isolates. Protein isolates are obtained from the corresponding flour by extraction with water. A pH of 6.5 – 7.0 is established in this process. As in the case of soybean protein isolates, subsequent precipitation from aqueous solution occurs at the isoelectric point (i.e., pH 4.2).

The protein isolates have remarkable emulsifying and foam producing as well as emulsion and foam stabilizing properties. Special purposes can be served by modifications of the protein isolates. For instance, high emulsifying and stabilizing properties can be generated by the *acetylation* of faba bean protein isolates. Both the foam producing capacity and the foam stability can be improved by *heat treatment* of faba bean protein isolates. Similar effects can also be achieved by *enzymatic partial hydrolysis.*

With faba bean protein isolates as an example, the composition and functional properties of these products are presented in Tables 15 and 16. The applications of these protein isolates correspond to those of soybean isolates.

Producers and Trade Names of Leguminous Protein Products. Different types of faba bean and chick-pea flour are commercially available (see Table 17). This applies also to textured faba bean flour, textured faba bean protein concentrate, and pea protein isolate.

2.2. Protein Products from Roots and Tubers

Root and Tuber Producing Countries. The production of roots and tubers in 1989 and the principal countries involved are shown in Table 18.

Main Nutrient Content and Protein Nutritional Value of Roots and Tubers. The protein content of the roots and tubers listed in Table 19 is less than 2.5 wt % (about 10 wt % of

the dry weight). The biological value of the proteins is generally good. In normal nutrition, roots and tubers really represent a source of starch. They become simultaneous suppliers of protein on their large-scale processing to starch. This applies especially to potatoes (see also → Starch). The potato protein water ob-tained during processing to starch can represent a real wastewater problem because it enhances microbial growth. For this reason, it is used for the isolation of protein in modern starch production plants.

Isolation and Uses of Potato Protein Products [56] – [2.57 a]. Protein is normally precipitated from potato protein water (protein content 2 – 4 wt %) at pH 4.7 – 6.0 by steam injection at 80 – 120 °C. The separated coagulate is washed with water and spray-dried. Potato protein concentrates of this type contain 78 – 89 wt % of protein and 7 – 8 wt % of fat. This product is brownish, tastes like raw potatoes, and has no favorable functional properties. It is used as feed in calf breeding because of its good protein nutritional value [net protein utilization (NPU) = 73].

Table 18. Production (in 1000 t) and principal root and tuber producing countries 1989 [49]

[c] NPU (net protein utilization).
[d] PER.

In principle, potato protein represents a source of protein for direct use in human nutrition. The necessary work to achieve this can essentially be regarded as concluded. This refers primarily to the inactivation of phenol oxidases, separation of lipoproteins in potato protein water, precipitation of proteins at 70 – 80 °C, and lipid extraction of the protein coagulate. In this process, protein isolates with protein content of > 90 wt % and fat content of < 1 wt % can be obtained. At the same time, the functional properties (including taste and color) are improved to such an extent that the use of these proteins in the production of food should be possible.

2.3. Leaf Protein Products

Protein Content and Protein Nutritional Value of Leaves. The selection of plants presented in Table 20 shows that in principle the leaves of all agricultural plants can be used for the isolation of proteins. The possible use as a protein raw material is determined finally by the following factors: protein content, extractable portion of proteins, protein nutritional value, and possibility of eliminating plant components that present a health hazard.

Table 20. Protein content and extractable protein (% of dry weight) of leaves [64] and biological value of protein [54]

	Protein content	Extractable protein	Biological value
Castor bean	41.3		
Chick-pea	31.8

Isolation and Use of Leaf Protein Concentrates from Lucerne and Clover, Trade Names. The possibilities for the preparation of leaf protein concentrates are summarized in Figure 5. The proteins can be obtained from the leaf extract ("green juice") by heat or acid precipitation, by formation of insoluble complexes with pectin or carboxymethyl cellulose or by ultra- or diafiltration.

Until now, most research has been devoted to the isolation of proteins from lucerne and red

Figure 5. Isolation process for leaf proteins [54, 67]

Table 21. Composition of differently isolated leaf protein concentrates [69, 72–76]

	Protein, wt %	Fat, wt %	Carbohydrate, wt %

Precipitation with pectin at pH 6.2	20		55
Precipitation with carboxymethyl cellulose-Na at pH 6.2	22		51

and white clover. The composition of the corresponding protein concentrates is presented in Table 21.

Leaf proteins with good functional properties are obtained by the ultra- or diafiltration of chloroplast-free extracts. Colorless lucerne protein concentrates isolated in this manner are water soluble at pH 2.0 – 2.5 and above 5.0. The solubility at pH 6.2 (solubility 95 wt %) is reduced by addition of NaCl; 2.0 mol/L NaCl decreases the solubility to 70 wt %. The proteins are heat stable up to 50 °C.

In principle, leaf protein concentrates are suitable for human nutrition.

Trade Names. Several production plants exist that are based on lucerne as raw material. In the United States, Pro-Xan (total lucerne protein concentrate) and the Pro-Xan II product series are produced. The latter include a green lucerne protein concentrate (chloroplast protein concentrate) and a colorless lucerne protein concentrate (cytoplasma protein concentrate).

The product Vepex (total lucerne protein concentrate) was produced in Hungary. This concentrate was also available as a mixture with 30 wt % skim milk powder (Velac). "Total" Proxan as well as "green" and "colorless" Proxan contain xanthophyll and are used as special animal feed for poultry.

The water solubility of the proteins contained in Proxan and Vepex at pH 2 – 10 is ca. 5 wt %.

2.4. Health Aspects

2.4.1. Antinutritive Factors in Plant Protein Raw Materials

The important antinutritive factors are listed in Tables 22, 23, 24, 25, 26 for cereals, legumes, roots, and tubers. Some antinutritive factors are found in almost all plant protein raw material. This applies to enzyme inhibitors (inhibition of the digestive enzymes trypsin, chymotrypsin, and α-amylase), lipoxygenases [*9029-60-1*] (off-flavor formation from unsaturated fatty acids), isoflavones [*4737-27-3*] (estrogenic action), hemagglutinins (lectins [*103938-95-0*], blood coagulation), tannins (bitter taste), phytic acid [*83-86-3*] (reduction of the bioavailability of zinc and iron ions), phenol derivatives (e.g., sinapine [*18696-26-9*] and chlorogenic acid [*906-33-2*], reduction of the biological value of the protein), nitriles (formation of hydrogen cyanide), and the oligosaccharides raffinose [*512-69-6*], stachyose [*470-55-3*], and verbascose [*546-62-3*] (flatulence producing).

Specific antinutritive factors are of significance for particular plant protein raw materials. This applies to gossypol [*303-45-7*] in *cotton seeds* (inhibition of spermatogenesis), to 5-vinyloxazolidine-2-thione [*13190-34-6*] (thyrotoxic) formed from glucosinolates

(glucobrassicin [*4356-52-9*]) in *rapeseeds*, to 1-amino-D-proline [*10139-05-6*] (antipyridoxin effect) formed from the peptide linatine [*10139-06-7*] in *linseed,* to the favism factors vicine [*152-93-2*] and convicine [*19286-37-4*] (hemolytic anemia in case of glucose-6-phosphate dehydrogenase deficiency) in *faba bean,* to lupanine [*550-90-3*] and sparteine [*90-39-1*] in *lupines* (CNS excitation, paralysis, muscular stimulation, bitter taste), to α-solanine [*20562-02-1*] and α- chaconine [*20562-03-2*] in *potatoes* (diarrhea with vomiting, nephritis, cerebral edema, cramps, coma, bitter taste, and off-flavor), to dioscorine [*3329-91-7*] in *yam*, as well as to the bitter substance 2-hydroxyarctiin [*20362-31-6*] and to the laxative 1-matairesinoside [*23202-85-9*] in safflower.

In principle, lysinoalanine [*18810-04-3*] (nephrocytomegaly) can be formed in the processing of proteins, especially in an alkaline environment.

The formation of highly toxic metabolic products of mold fungi – mycotoxins – must also be considered for a series of plant protein raw materials. For instance, the real toxicological problem with peanuts is the possible aflatoxin content (liver damage).

All the plant protein raw materials listed here are used to a greater or lesser extent in human nutrition; this also applies to proteins made from these materials. The problems mentioned above can be minimized or even eliminated by the proper storage of raw materials and by the use of processing principles adjusted to the antinutritive factors (inhibition of their formation, removal by degradation, or extraction).

2.4.2. Minimization of Antinutritive Factors in Processing Selected Plant Protein Raw Materials

Cereals. Although protease and amylase inhibitors occur in cereals, their concentrations are relatively low. Cereals contain only ca. 1 % of the amount of trypsin inhibitors found in soybean. Moreover, a large portion of these inhibitors is heat sensitive. Therefore, these raw materials do not present a health risk in human nutrition. Even the phytic acid concentration is tolerable, as shown by daily nutrition.

However, the fact that some people are sensitive to cereal proteins is of great practical importance. The mucosa of the upper small intestine is flattened by the prolamins in the gluten of wheat (gliadin [*9007-90-3*]), rye (secalin), barley

(hordeine [*99550-00-2*]), and oats (avenin). This results in a reduced resorption capacity of the upper small intestine and malabsorption (i.e., in celiac disease). The prolamines of rice, maize (zein), millet, sorghum (kafirin), and buckwheat do not cause celiac disease.

Soybeans. Raw soybeans and untreated soybean flour (fatty and defatted) contain a series of antinutritive factors. During the production and processing of soybean products, these factors can be inactivated by destruction, extraction, or addition of inhibitors, which either directly inhibit the factors or neutralize their activity. Thus, *heat treatment* is used to substantially reduce the activity of hemagglutinins (in fatty soybean flour from 330 to 13 units per milligram of protein)

and trypsin inhibitor (in defatted soybean flour from 80 to 10 units per milligram of protein). The goitrogenic activity (low molecular oligo- or glycopeptides), the antivitaminogenic activity (e.g., rachitogenic activity), and the mineral-binding capacity of phytate (results have been obtained for calcium, phosphorus, zinc, iron, manganese, copper, and molybdenum) are partially reduced by heat treatment. At the same time the available lysine is reduced (from 5 to 2.5 g/16 g of nitrogen), and the nutritional value of the protein is increased (for defatted soybean flour the digestibility is increased from 74 to 84, the biological value from 52 to 65, the PER from 0.5 to 1.9, and the cystine [*56-89-3*] availability from 45 to 75 %). Thus, pancreatic hypertrophy (see below) is prevented. In contrast to the lectins of other leguminous plants, the hemagglutinin activity of soybean has no connection with its protein value. The improvement in the nutritional value of the proteins resulting from the heat treatment of soybeans or their products is due to the destruction of trypsin inhibitors and denaturation of the proteins.

Pancreatic hypertrophy is caused by hypersecretion, which is a result of a reduction of active trypsin in the intestinal tract due to the formation of a trypsin – trypsin inhibitor complex in the presence of undigested protein. The goitrogenic residual activity of soybean protein after heating can be compensated for by iodine supplementation (potassium iodide). Supplementation with vitamin D or minerals is possible in the case of any remaining rachitogenic activity or the limited availability of minerals. No effect is achieved by iron supplementation with iron sulfate. On the other hand, iron pyrophosphate can be used to increase iron availability up to 90 %.

For the use of soybeans and soybean products in human nutrition, the fact that undigested oligosaccharides, primarily stachyose but also raffinose, cause increased gas production (flatulence) due to anaerobic fermentation is still important. Although soybean flour (defatted flour: 5.5 wt % stachyose, 1.1 wt % raffinose) still exhibits a marked effect, this is no longer the case with concentrates (1.8 wt % stachyose, 0.5 wt %

raffinose) after extraction of the active oligosaccharides.

Casein, lactalbumin, ovalbumin, beef or pork proteins can be shown to be more cholesterolemic and atherogenic than soybean, peanut, or wheat proteins, for example. However, the activity of these plant proteins is considerably influenced by other food components. While the lower effect of soybean proteins is retained on interaction with saturated fat, dextrose, or cellulose, adaptation to the higher activity of animal proteins occurs with potato starch or lucerne. It has been found that the cholesterolemic and atherogenic effect correlates with a high lysine : arginine ratio (casein 2.0, lactalbumin 2.6, soybean protein 0.9, and wheat proteins 0.4). Since lysine inhibits arginase activity in the liver, a hypothesis has been proposed that due to this inhibition a high lysine content results in greater arginine availability for the synthesis of an arginine-rich apoprotein, which is a component of a lipoprotein with atherogenic activity.

Long-term studies on humans have shown that when used as the main or even sole protein carrier, soybean proteins are, in practice, equally suitable for infants, children, young people, and adults. If the products are made carefully, supplementation with sulfur-containing amino acids is not necessary. Supplementation with methionine [*63-68-3*] is recommended only for newborns as a precautionary measure.

Faba Beans and Peas. As described for soybeans, the antinutritive factors of faba beans and peas can be minimized or eliminated by heat treatment and separation processes (extraction, precipitation, membrane separation). This also applies to vicine and convicine from faba beans. However, if protein and starch are enriched by air classification, an enrichment of antinutritive factors and off-flavor also occurs.

Potatoes. The toxic factors contained in potatoes are glycoalkaloids (especially α-solanine and α-chaconine), hemagglutinins (lectins), and trypsin and chymotrypsin inhibitors. The glycoalkaloids are found primarily in the skin and are, consequently, partially eliminated by peeling the potatoes. An acceptable glycoalkaloid content is 6 – 20 mg per 100 g of fresh potatoes, but the average concentration in cultivated potatoes seldom exceeds 10 mg/100 g. The hemagglutinins and protease inhibitors are almost completely destroyed by heating. Thus the toxic components of potato are largely eliminated during the production of potato protein concentrates (precipitation from solution and heat treatment).

Lucerne and Clover. White clover contains linamarin (2-hydroxyisobutyronitrile-β-D-glucopyranoside) [*554-35-8*] and (*R*)-lotaustralin (2-methyllinamarin) [*534-67-8*]. During the destruction of leaf tissue, the glycoside is cleaved by the endogenous enzyme linamarase [*9031-18-9*] (EC 3.2.1.21) and hydrogen cyanide can be formed. Hydrogen cyanide-forming capacities of between 3.2 and 3.52 ng per gram of fresh weight have been found in clover. The toxicity is reduced considerably by the destruction of the leaves and heating. In human beings, poisoning can occur at concentrations between 0.5 and 3.5 mg of hydrogen cyanide per kilogram of body weight.

L-Canavanine (2-amino-4-guanidinoxybutyric acid) [*543-38-4*] has been found in lucerne. It acts as an arginine antagonist and interferes with the metabolism of ribo- and deoxyribonucleic acids. The toxic effect of this component is minimized by heating.

Lucerne and red clover also contain estrogenically active isoflavanoids, especially coumestrol [*479-13-0*] (lucerne: 57 ppm, clover: 49 ppm) and formononetin [*485-72-3*] (lucerne: 14 ppm, clover: 38 ppm). These phytoestrogens are heat resistant. The exposure of humans to these exogenous estrogens is very slight (about 1/1000 of the hormone equivalent of conventional oral contraceptives). These toxic components are most likely minimized considerably by the precipitation of lucerne and clover proteins. Therefore, such protein concentrates have been employed successfully in human nutrition.

2.4.3. Food Laws

During its 18th meeting in Geneva (July 3 – 14, 1989), the Codex Alimentarius Commission approved "Guidelines for the Use of Non-Meat Protein Products in Processed Meat and Poultry Products." According to these guidelines, standardized nonmeat protein products can be employed in principle for functional and other pur-

poses and for the partial substitution of meat proteins [92].

In this connection, a general standard for plant protein products and recommendations for international standards for soybean protein products and wheat gluten have been elaborated. In fact, the following minimum values with regard to the raw protein content (N×6.25) have been stipulated [93].

Plant protein product	40 wt %
Soybean protein flour	50 wt %
Soybean protein concentrate	65 wt %
Soybean protein isolate	90 wt %
Wheat gluten	80 wt %

National legal regulations for the use of plant protein products in foods vary considerably. A compilation is contained in the report "Plant Protein Production and Its Use in Human Nutrition" of a working party at the fifth meeting of the Codex committee for plant proteins in Ottawa (February 6 – 10, 1989) [94, 95].

2.5. Proteinaceous Products from Microalgae

The exploitation of natural stocks or of mass cultures of larger marine algae (seaweeds) serves as a basis for important industries (e.g., in California and Japan) that produce mainly alginates, carrageenates, or agar (→ Polysaccharides). In addition *red* and *brown marine algae* are highly valued in eastern Asia and considered a delicacy [96], stringy *green algae* are consumed, e.g., in southern Asia. Red and brown algae contain little protein in comparison to edible green algae [97]. The masses of the *blue-green alga Spirulina* occurring in Lake Tchad are used as a local supply of protein [98].

Of the thousands of species of microalgae that occur in inland waters or seas, only a few have been produced in mass cultures until now [99]. The yields per unit area depend on the solar irradiation and the temperature. Year-round production is possible only in warm countries.

Dried microalgae from mass cultures are internationally traded and sold as specialities ("natural pharmaceuticals," etc.) in the form of protein-rich pills or, more often, powders. Despite the relatively high protein quality of microalgae meals, prices of at least $ 14/kg preclude wider application. Nevertheless, protein-rich microalgae are of considerable importance because they are also produced in wastewater (e.g., in Southeast Asia) and are used on the spot to produce fish or animal feed, without being put on the market.

The algae – bacteria biomass obtained from wastewater until now has been used systematically as feed only in individual cases [100]. It contains about 10 – 40 wt % of bacteria, flagellates, or other nonalgal components.

Properties. *Physical Properties.* Microalgae meals (residual water 5 ± 2 wt %) [99] have a more or less intensive green color because of their chlorophyll content. Meals from blue-green algae are more bluish green because they contain the water-soluble pigment phytocyanin. The microalgae biomass produced for the isolation of carotinoids has a bright orange color in the case of *Dunaliella* species (β- carotene) and a brick-red color in the case of *Haematococcus pluvialis.* The consistency of microalgae meals is finely powdered when the raw mass has been freeze dried or spray dried and flaky after drum drying. With drum-dried material, the initially very low bulk density can be doubled by mechanical compacting (Table 27).

The water-binding ability of microalgae meals is relatively high and is influenced by the type of drying. Good nonoverheated products bind approximately 5 L of water per kilogram of dry substance [101].

Chemical Composition. The composition of microalgae products is variable and is influenced by the culture conditions and the climate (e.g., Table 9.1. in [102]).

Although seaweed dry matter sometimes contains relatively little protein (Table 28), microalgae are among the most protein-rich plant raw products (Table 29). Blue-green algal substance differs from the comparable green algal substance in that it has a lower lipid content.

As calculated from the sum of the amino acid concentrations, protein nitrogen accounts for 87 ± 2 % of the total nitrogen of *Spirulina* and 89 ± 2 % of the total nitrogen of *Scenedesmus.*

Due to the analytical techniques employed, data on the amino acid content are subject to uncertainties in measurement (Table 30), e.g., in the case of the important amino acid methionine. For this reason, the protein value determined nutritionally and physiologically might

Table 27. Bulk densities of some microalgae meals (original values)

Yeast powder (*Candida lipolytica*)	64	9	15	7	8
Soybean seeds	34 – 40	16 – 20	19 – 35	4 – 5	?

be a more reliable criterion of quality. Microalgae sometimes contain small amounts of rare amino acids [101] that are apparently lacking in higher plants.

Details on the composition of the lipid fraction (fatty acids, etc.) and the high vitamin concentrations in microalgae meals are given in [99]. The β- carotene concentrations in *Dunaliella salina* reach 14 % under salt stress [106]. *Scenedesmus* and *Spirulina* meals contain 1.3 –3.3 and 0.6 – 0.8 % chlorophyll and 0.3 – 0.7 and 0.3 – 0.4 % total carotenoids (based on dry matter), respectively. The xanthophylls, which may cause problems in the feeding of green algae to poultry, can largely be destroyed by thermal pretreatment of the raw product.

Production. Like all photosynthesizing plants, algae require light, carbon dioxide, and minerals for growth. *Mesophilic algae* grow best up to ca. 30 °C, whereas the optimum temperature for *thermophilic algae* is 35 – 40 °C. Algae that *grow autotrophically* utilize carbon dioxide as the almost exclusive source of carbon on exposure to light. Many microalgae are also capable of *heterotrophic growth* (i.e., they can utilize organic compounds in the dark). Several microalgae also show *mixotrophy* (i.e., on exposure to light, they utilize both CO_2 and dissolved organic substances). The culture solution must be cir-culated to attain good yields and prevent sedimentation.

Clean methods for the production of microalgae are characterized by the fact that the composition of the culture solution is largely defined. This ensures the production of pure species and high-quality products. Microalgae are frequently produced in batch culture. The culture solution is based on fresh water (for *Chlorella*), on alkaline brackish water (for *Spirulina*) or on seawater (for *Dunaliella*).

In the *continuous wastewater processes* for the production of microalgae, liquid waste or wastewater is the source of nutrients. The algae – bacteria biomass that accumulates as a byprod-

Table 30. Concentrations of the most important amino acids in green algae meal (*Scenedesmus obliquus*) and blue-green algae meal (*Spirulina maxima*) compared to average values for fodder yeast (*Candida lipolytica* made by BP), extracted soybean meal, and fish meal (values in g/16 g of total nitrogen, according to [110] and [111])

Amino acids	*Scenedesmus*	*Spirulina*	BP yeast	Soybean meal	Fish meal

uct of wastewater treatment can be used as a component of animal feed [107].

Figure 6. Production of algae meal from microalgae

Culture tanks for outdoor operation are available in many different designs [99, 108]. Horizontal raceway ponds made of concrete with a paddle-wheel circulation are usually preferred. The most advantageous depth of water is 10 – 15 cm for autotrophic "clean" cultures and 40 – 60 cm for wastewater systems. Meandering channels on inclined surfaces [109] presumably require less mechanical energy per hectare than horizontal troughs. Closed culture units consisting of meandering tubings or sandwich structures offer the possibility to produce very pure microalgae biomass at cell concentrations that are at least ten times higher than in open basins. For basins used in the wastewater process, the earth can simply be excavated and the resulting basin sealed with a layer of clay.

The pure carbon dioxide used for autotrophic cultures contributes considerably to production costs. It can, however, be replaced by CO_2-rich waste gas (e.g., from the production of ethanol [110]). A flow diagram for the production of algae meal from microalgae is shown in Figure 6. Details can be found in [99, 107, 108]. Cultivation is followed by separation and processing of the raw algae mass into the particular final product. During processing, the raw mass is sterilized by flash pasteurization. In the case of green algae, this step is absolutely necessary to make the product sufficiently digestible.

Separation is especially laborious because the cell suspensions contain very little solid matter (0.04 – 0.1 %). Before further processing, the proportion of solid matter must be directly or gradually increased to at least 15 % and, if possible, to more than 25 % [110]. Coarse, particulate algae (e.g., *Spirulina*) can be separated by simple filtration. Flocculation and flotation are

suitable first steps in the separation of the algae – bacteria biomass from treated wastewater [111].

Quality Specifications. An algal product must pass a nutritional physiological and toxicological safety test before it can be put on the market as food or feed. International recommendations exist for these tests [101]. Special safety aspects apply to the use of algae – bacteria biomass from wastewater for animal nutrition [112].

Producers. Among the numerous East Asian producers of *Chlorella* are Sunpack Co. Ltd., Tokyo, Japan; China Chlorella Industry Co. Ltd., Changhua, Taiwan.

Important producers of *Spirulina* meal are SOSA Texcaco SA, Mexico and Siam Algae Ltd., Bangkok, Thailand.

The German importers of microalgal products are Dr. Winfried Behr, Bonn, and Sanatur GmbH, Engen, Federal Republic of Germany.

Storage. Fresh microalgae meals have a weak, vegetable, largely neutral taste that is lost within a few days on exposure to air because, especially in the case of green algae meals, they quickly become rancid due to autoxidation [113]. Therefore, the products should be vacuum packed or stored under an atmosphere of protective gas. Decay is prevented if fresh algae meal or heat-digested algae mass is processed into pellets or pasta. Final products of this type retain a perfect taste quality even after several years of storage.

Uses. Approximately 3000 t of microalgae meal are put on the market each year. Roughly half of this amount is processed into natural pharmaceuticals in Japan, Korea, Taiwan, Europe, and the United States (*Chlorella* tablets, powder, and extract; *Dunaliella* tablets for cancer prophylaxis; and *Spirulina* tablets). The other half (including ca. 1500 t/a of *Spirulina* meal from Mexico) is used for aquaculture (cultivation of fish, mussel, and shrimp larvae, addition to aquarium-fish feed, etc.). In many places in Southeast Asia, algae – bacteria suspensions from wastewater ponds are added to pig, fish, or poultry feed. The amount of algae used for these applications is probably several times larger than the total volume of commercially produced microalgae meal. The addition of algae suspensions to the water of cattle, which has been practiced in southern Russia for decades, promotes a weight increase in the animals and stimulates milk production [114].

Nutrition Physiology, Toxicology. All the microalgae meals tested are good sources of protein for rats, pigs, carp, grass carp, and even humans [101, 107, 108]. In the feeding of chicken, however, not more than half of the conventional protein carriers can be replaced by microalgae protein without causing a definite reduction in growth rate.

The microalgae products that have been toxicologically tested more carefully (especially *Chlorella, Scenedesmus,* and *Spirulina*) until now have been considered toxicologically safe, provided that no harmful substances from the fertilizer or the environment have accumulated in them [101]. If microalgae are used to a significant extent in human nutrition, the amounts must not exceed certain safety limits because of their high nucleic acid content (ca. 4 % based on dry substance).

Economic Aspects. Profitability calculations and cost analyses of the various microalgae processes are given in [99, 107], and [108]. Pure microalgae meal costs about $ 14 – 20/kg. To sell substantial amounts of algae meal on the feed market, the present retail price must drop to less than $ 0.60/kg. This would be possible, if at all, only for production on a wastewater basis.

3. Animal Proteins

3.1. Fish Protein Concentrates (FPC) [115–119]

More than 25 % of the world's fish catch is converted into animal feed [120]. Fish proteins are among those with high nutritional value. That is why processes are intensively being investigated that might be suitable for direct production of human food from sources that are normally used to prepare fish meal. The different protein classes contained in cod (in wt % of crude protein) are listed as an example in what follows [121]:

Sarcoplasmic proteins	20 – 30
Myofibrillar proteins	65 – 75
Myosin	40
Actin	15 – 20
Tropomyosin	3
Collagen	2 – 5
Nonprotein nitrogen- containing compounds	13 – 14

To achieve a satisfactory shelf life for fish-based products, most of the fat and water must be extracted from the raw material. Isolation of certain protein classes is not a goal. Depending on the process used, nonprotein nitrogen (NPN) substances and varying proportions of the sarcoplasmic proteins are removed. Proteins may also be hydrolyzed or modified by chemical reactions.

The dewatered and defatted fish protein concentrates (FPCs) are powdery and vary in color from white to brown; they either are odorless or exhibit fishy, rancid, or oily notes. According to the Protein Advisory Group of the FAO, three types of solid FPCs are defined (see Table 31); liquid concentrates are of no importance. The term fish protein concentrate should not be used for fish sauces produced in the Far East. Also dried, salted, or smoked products, which still exhibit anatomical macrostructures (such as klipfish, stockfish, and other dry fish products) are not included in this term (even though these products have an increased protein content). In this section, only those products are treated whose technological or quasi-technological production data has been published.

Table 31. FAO requirements for fish protein concentrates [122]

	Type A, %	Type B, %	Type C (fish meal)
Lipids	< 0.5	*	
Moisture	< 10	< 10	no requirements
Protein	> 75	> 60	
Ash (acid soluble)	< 0.5	< 0.5	
Fluoride	< 250 mg/kg	< 250 mg/kg **	
Available lysine	> 6.5	> 6.5	

* No limitation.

** The FDA in the United States requires an upper limit of 100 mg/kg; the Food and Drug Directorate in Canada, an upper limit of 150 mg/kg [115].

3.1.1. Raw Materials (see Table 32)

The first attempts to produce FPC were performed with lean fish species such as cod [123] or less fatty fish such as hake [124]. Currently these valuable fish species are converted aboard trawlers into quick-frozen (QF) fish fillet products and therefore are not used for FPC. Species that are underused or not used for direct human consumption and thus are a possible source of FPC include a number of small- to medium-sized pelagic, mostly fatty fish (scombroids, anchovies, sardines, menhaden, capelin, sand eels), deep-sea fish (*Myctophidae*), and antarctic krill [131]. Possible catches of these species can be estimated only roughly:deep-sea fish up to 10^8 t/a, squid 10^7–10^8 t/a, and krill ca. 10^6 t/a (the world catch of aquatic animals in 1989 amounted to 99 534 600 t, including 13 776 700 t from aquaculture and inland fisheries [120]).

Use of offal from fillet production lines is of no importance because of the low amounts available and the undesirable composition of the resulting FPC (high content of fluoride and phosphates, off- color). The use of freshwater fish as raw material has also been described [132, 133].

In the United States and Canada legal restrictions govern which species may be processed into FPC: in the United States, herring-type fish (clupeids), hake species, menhaden, and California anchovy; in Canada, osmerids such as capelin and smelt, as well.

Fish stocks that may be used for the production of FPC must be accessible for the entire year to keep production capacities as constant as possible and must be available in large quantities to guarantee homogeneous raw material. A single production plant should process at least 500 t of raw material daily in order to be economical. A program for calculating the optimal design of the technological process and the process parameters is available [134].

3.1.2. Production [116, 135]

Many different processes have been proposed for the preparation of *low-fat FPC* (*type A,* Table 31). Despite differences in details, these processes are all based on three common principles:

1) Enrichment of protein content
2) Reduction of microbial growth by decreasing water content
3) Stabilization of the product against alterations due to chemical reactions of lipids by removing most of these

Table 32. Composition of marine raw material (wt % based on wet weight)

	Crude protein (N×6.25)		Edible part		Reference
	Whole fish	Edible part	Fat, wt %	Ash, wt %	
Lean fish		13 – 24	0.1 – 0.9	0.7 – 1.4	[121, 125]
10 species	15.3 ∗ (12.7 – 17.2) ∗∗	17.3 ∗ (15.2 – 18.9) ∗∗			[116]
Fatty fish		17 – 22	9 – 18	0.7 – 1.4	[121, 125]
Mollusks		9 – 20	0.3 – 4.8	1.6	[121, 125]
Squid		16 – 20	0.8 – 2.2	1.2 – 1.7	[121, 125], [126–128]
Crustaceans		7 – 23	0.2 – 4.5	0.5 – 1.3	[121, 125], [129]
Krill		13.4	1.6 – 7.0	3.2	[130]

∗ Average. ∗∗ Variation.

The fat and water content can be reduced by different combinations of heating, extraction, application of pressure, and drying. The flow diagram given in Figure 7 as an example may be modified by leaving out some steps or inserting others.

The raw material is highly perishable and should be processed immediately after landing; alternatively, it may be stored chilled. If extraction is used as the first processing step the raw material can be stored as a mixture with the extraction solvent [136]. Removal of bones from the raw material by bone separators is recommended; this lowers the ash content of the resulting FPC from 14 – 20 wt % to 3 – 6 wt % and the fluoride content from a maximum of 760 mg/kg to 60 – 160 mg/kg. Simultaneously, its protein content increases from 80 to 90 wt % [135, 137]. Separation of bones from the final FPC is ineffective and results in lower yields.

Decanting. After coagulation of protein by heating at 80 – 100 °C, part of the water and fat may be removed by decanting the liquid components in centrifuges or in screw presses. This procedure is identical to that used in the production of fish meal.

Extraction. Alternatively, most of the *fat and water* may be removed by extraction with 2-propanol, 1,2-dichloroethane, xylene, *n*-octane, *n*-butanol, or *tert*-butanol. However, only the first two solvents have been used on a technical scale [138, 139]. The protein quality reportedly deteriorates when 1,2-dichloroethane is used as extractant [137]. Processes involving two solvents or the removal of water by azeotropic distillation are more costly and have not been inves-tigated widely. Water and fat can be extracted from dried raw material such as fish meal by 95 % ethanol [140]. A preextraction with *n*-hexane which improves the product has been reported [141].

If residual water and fat are to be removed from the press cake or if unpressed material is to be processed, only solvents that are at least partly miscible with water [i.e., acetone, 2-propanol, *tert*-butanol, methanol, ethanol, glycol monomethyl ether (Cellosolve), and dioxane] can be used for extraction. Of these, only 2-propanol and ethanol have been applied successfully. The other solvents lead to residues in the extracted material; acetone contributes a permanent off-odor. 2-Propanol cannot be efficiently removed from the extracted material simply by drying; however, its content could be lowered from 10 000 mg/kg to 30 mg/kg by addition of water to the material and repeated drying or by steam distillation. Countercurrent extraction and dewatering have been applied successfully [142].

Detergents such as dodecyl or lauryl sulfate remove *fat* at 65 °C; the high content of detergent (up to 40 %) that remains in the FPC is a disadvantage [143].

A similar problem is encountered when the raw material is suspended in fish oil (as heat carrier) and water is removed at 66 °C in a vacuum thin-layer evaporator. The product still contains > 12 wt % fat after pressing and must be defatted by an additional extraction [144]. The advantage of this process is that it can be run at reasonable costs and leads to an FPC that contains the water-soluble constituents of fish; however, these constituents may lead to storage problems because of microbial attack or devel-

Figure 7. Flow sheet for the preparation of fish protein concentrates (FPC and FFPC)

opment of off-odors [145]. In some processes, these substances are extracted by dilute acids (hot acetic acid, phosphoric acid, or cold hydrochloric acid with sodium chloride) prior to fat extraction [123, 146, 147].

Flocculation. Flocculation of the major part of lipids as lipoprotein complexes by solubilizing the raw material with alkali and acidifying the solution to pH ≤ 5.5 has also been reported [148]. This method can be used only if completely soluble protein hydrolysates are produced. They are then obtained by evaporation of the residual solution. Only a low yield of proteins is obtained by further acidification of the solution after flocculation. By adding sodium hexametaphosphate at pH ≈ 4 a phosphate-containing protein precipitate can be separated from the oily – watery supernatant by centrifugation (fish contains ca. 80 % oil and water). Washing the centrifuge residue with an azeotropic mixture of water and propanol yields a satisfactory protein concentrate, with a phosphate content exceeding by only 1 % that of FPC prepared by extraction [149].

Bleaching, Drying, and Final Processing. The fish protein concentrates can be bleached with hydrogen peroxide at pH 8 to 9.5 [148, 150–152]. Drying may take up to 2 h at up to 120 °C without substantial deterioration of the nutritive value of the protein [153, 154]. The water-solubility and the emulsion stabilizing properties of the protein decrease when drying temperatures increase from 90 – 100 to 110 – 120 °C [155]. The unavoidable removal of solvent residues by water vapor also leads to a remarkable decrease of these two functional prop-

erties. Recovery of the solvent is essential for process economy: otherwise up to 10 % of the solvent used may remain in the extracted product. The construction of drying facilities must guarantee good hygienic conditions; otherwise the plate counts of aerobic microorganisms in the product will increase rapidly. If countercurrent extraction with 2-propanol is used the bulk of the fish oil can be recovered by centrifuging. For this purpose the extract from the last extraction step, which is hot and rich in oil, is mixed with the extraction mixture from the first step, which contains the cold fish. The two phases that form are separated in a centrifuge. When 2-propanol is recovered by distillation, phosphoric acid must be added to the mixture to be distilled to neutralize the basic compounds contained in fish (di- and trimethylamine). Milling of the resulting FPC to 200 mesh (74 µm) is necessary for many purposes to avoid a sandy mouthfeel.

Functional Fish Protein Concentrates (FFPC). The term functional fish protein concentrate applies to an FPC prepared in such a way that it still possesses some properties that are valuable for its technological use and are characteristic of native proteins. Examples are foam formation, coagulation, formation and stabilization of emulsions, and water-binding capacity. An FFPC with good rehydration and emulsification properties can be produced if all the processing steps described above are performed below 52 °C [150] and 2-propanol is removed by warm air saturated with water vapor [156]. The FPC produced by extraction of raw material with ethanol – hexane at pH 2.5 in the presence of 5 wt % NaCl also exhibits emulsification and rehydration capacities [157]. An FFPC has been prepared from krill meat by extracting the meat twice with a fourfold amount by volume of ethanol at 5 – 10 °C in the presence of 1 – 2 % NaCl at pH 7.4 – 7.6 (addition of $NaHCO_3$). A completely soluble FFPC has also been prepared from minced krill meat by extraction with 2-propanol, alkaline digestion at 37 °C and pH 10.5, and subsequent freeze drying: this material exhibits good emulsion and foam-forming properties [158].

Another approach for preparing FFPC uses chemical reactions to reintroduce functional properties into the protein that has been denatured by the normal preparation of FPC (see also Fig. 7). Addition of alkali [123] or proteolytic enzymes [140, 141, 159, 160], as well as acetylation and succinylation of the nucleophilic side chains of proteins [161–163], have been described among others. When alkali is used the formation of toxicologically hazardous lysinoalanine [164] must be monitored carefully.

A singular method for reintroducing functional properties to FPC is milling the product in a ball mill for 100 h [165]; the product is reportedly suitable for forming a resilient *kamaboko* (a Japanese product usually prepared from minced washed fish by grinding and adding NaCl and starch) [166]. Many reports state that the functional properties of FFPC decrease with time [167]: to some extent this can be prevented by the addition of carbohydrates (corn syrup, glucose, sorbitol) prior to drying the FFPC. In contrast, an unchanged quality has been reported when FFPC from filefish [168] and shark [169] was stored for three months at 25 °C, as well as for storage of powdered soup from anchovy and mussels [170].

Production of Fish Protein Concentrates with a Higher Fat Content (Type B). The high degree of unsaturation in fish lipids [171] is responsible for the very limited shelf life of fat-containing fish protein concentrates at normal temperature in air. This is one of the main reasons why type B products have not been investigated with respect to production, properties, etc. Another reason is that consumers in most industrialized countries dislike products with an intense taste or even a slight rancidity. A North American Air Defense Command (NORAD) study demonstrated, however, that people in other parts of the world think differently [172]. An FPC of type B can be obtained rather simply by heating the fish to 95 °C, followed by separation of the protein in a decanting centrifuge or pressing device [173]. This product contains 7.1 –8.8 wt % fat and is storable up to two years. Fish protein that is to be mixed with starch- containing foods is preferably dried in a drum dryer (20 s at 150 °C surface temperature) because this method gives a product with good swelling properties [145]. The use of FPC type B in Africa, Asia, the Far East, and the Caribbean has been described [172].

If the raw meat is kneaded with the addition of NaCl (ca. 1 %) and extruded into ethanol at

5 – 30 °C, a product with a defined texture can be obtained, which is suitable for replacing part of the beef in hamburgers [174, 175]. Extraction with ethanol at − 20 °C, followed by extraction with hexane at − 20 °C, reportedly optimizes the functional properties [167].

Commercial Products. Norsildmel (Bergen, Norway) sells a fish protein concentrate type B (Norse Fish Powder) with 67 – 80 wt % raw protein, a maximum of 12 wt % fat, and ca. 100 mg/kg fluoride [176, 177]. All other production plants (some are cited in Table 33 that had been funded by FAO or by national governments ceased production after some time.

3.1.3. Nutritive Value

Fish protein concentrates have high nutritional value because of their high protein content and the protein's well-balanced composition of essential amino acids [121, 125, 179, 180]. The high lysine content of marine protein makes such products particularly well suited for fortifying a cereal-based diet, poor in lysine. The composition of fish protein concentrates is shown in Table 34. Both types, FPC A and B, not only are protein-rich foods of high value but also can contribute considerably to the daily mineral intake in the diet [180, 181, 183]. Fish protein concentrate type B provides a considerable supplement of zinc, calcium, iron, fluoride, iodine, and selenium, and is a good source of *n*-3 or ω-3 fatty acids (i.e., unsaturated fatty acids with double bond at C_3 of the carbon chain when counting from the methyl terminal group of the carbon chain), carnitine [183], and vitamins A, E, and the B group. The PER of an FPC from anchovy equals that of milk whey, whole egg, and mechanically deboned turkey meat, and is superior to egg white and different cereal flours [180]. In growth experiments with rats a high body weight gain has been demonstrated [140, 184].

3.1.4. Product Properties and Uses

The FPCs produced hitherto are not foods with a character of their own, but are added to other foods to reduce the content of more expensive protein sources or to fortify foods with protein. The use of functional FPC for introducing technological properties (e.g., froth forming, emulsifying, and swelling properties) has been demonstrated on an experimental, but not a commercial, scale. An overview of applications of FPC and FFPC is given in Table 35; other examples are provided in [185]. If FPC is used as a meat substitute in hamburgers, the increasing replacement of meat by FPC is often paralleled by a decreasing sensory rating [175, 186]. The substitution of a considerable part of beef in hamburgers (up to 50 %) by an FPC with limited functional properties from krill has also been described [193]; results of a sensory evaluation of the products are lacking.

3.1.5. Completely Soluble Hydrolysates from Fish Protein

The extensive hydrolysis of fish protein by different proteolytic enzymes has been reported frequently [196–206], although whether such a process has been performed on a commercial scale is unknown. The same holds true for alkaline hydrolysis. The only commercially available product of this type was the Wiking-Eiweiß [123], which was produced in Germany in the 1940s by alkaline digestion of cod fillet, followed by an extraction step with ethanol and dilute acetic acid. A slightly gray, odorless, easily digestible powder was obtained, whose taste was reminiscent of hen egg white. On heating, no coagulation of protein resulted, this product was used in mayonnaise, baked goods, sweets, ice cream, and pharmaceutical preparations.

3.2. Egg Proteins [207]

3.2.1. Structure and Composition of the Egg

Even in ancient times, egg was a popular food in all regions and religions of the world. Man almost instinctively chose a product that possesses excellent nutritive qualities. Being the germ for the development of a "new life" (embryo), the egg has an optimal composition and provides essential nutrients and active agents in an easily digestible form. It is also largely shielded from external influences because it is packed in its own shell, which accounts for about 10 % of the total weight. Although eggs from all types of poultry are edible and have all the qualities for human nutrition mentioned above, the word eggs usually refers to hen's eggs. These hens are bred and kept especially for laying and can produce an average of 300 eggs per year per animal.

The structure of an egg is described in Figure 8, the composition of various types of egg is given in Table 36. The average weight of a hen's egg is 60 g, the white and yolk contributing 58 and 32 %, respectively. Heavy eggs contain relatively more egg white than light eggs. Eggs are sold as fresh or shell eggs, either loose or packed in special boxes. In the EC, eggs are available in three grades of quality and seven grades of weight, according to quality regulations [208]. In addition, the three egg fractions white, yolk, and whole egg (i.e., total content of the egg or a mixture of egg white: egg yolk = 1.8 : 1) are available in various forms, namely, liquid, frozen, or dried and powdered. Additives such as salt or sugar are sometimes used. Egg products are subject to strict hygienic controls [209]. The contents of opened eggs must be pasteurized before they are processed further and can be put on the market.

The most important quality criteria of eggs include size, shape, color, shell stability, and inner properties (the latter quality criteria also apply to egg products). Inner properties include degree of freshness, utilization or functional properties (e.g., viscosity, foaming ability, and emulsion suitability), sensory properties (odor, taste, color) and nutrient content [210]. The nutrient composition of eggs, broken down into the major nutrients, minerals, vitamins, lipids, and amino acids, is listed in Table 37. This overview shows the impressive number of essential nutri-ents present in egg. That is why the protein composition of egg has been set as the basis for the optimum biological value = 100. A comparison of eggs with other foods is presented in Table 38.

3.2.2. Proteins in Egg

The chemical binding forms of egg proteins determine the material structure and especially the functional properties of eggs or egg fractions. Amino acids and other substances are united into large molecules, the proteins. Some of these

∗ The analytical data for eggs from other types of poultry should be similar.

form complexes with each other; the stability of these complexes depends on external conditions. This explains why the ratio of thick to thin egg white shifts constantly, the formation and stability of foam vary greatly, and gel formation and agglutination are subject to changes. The same applies to emulsifiability, which is mainly a characteristic of the yolk. The emulsifiability is a property of lipoproteins (i.e., compounds formed from proteins and fats).

Variations of functional properties are mainly caused by changes in temperature, pH, time (duration of storage), and their mutual interactions. With increasing storage time, the pH of the egg increases through CO_2 formation and its subsequent permeation through the shell, the solid matter and the proportion of yolk increase, and foam formation is improved. In contrast, the viscosity, foam stability, and proportion of egg white decrease. These processes are accelerated if eggs are stored above 8 °C [212]. The changes produced in liquid eggs due to pasteurization at high temperature are especially problematic. The difficulty is to choose an adequate temperature for eliminating microorganisms (especially *Salmonella*) while avoiding temperatures that could deteriorate functional properties. The instructions for pasteurization must be adhered to strictly and are checked mainly on the basis of temperature and holding time. An example is given in Table 39 [213].

The original properties of these fractions can be maintained largely by addition of organic acids, metal ions, or salt. With viscosity as an example, Figure 9 shows how final products can differ from each other depending on their pretreatment. In a larger experiment with exactly defined egg material, the variations (in %) given in Table 40 were measured for some quality criteria [213].

3.2.2.1. Proteins in Egg White

Due to improved electrophoretic techniques, the identification of proteins in egg white has made substantial progress [213]. Initially only the most important fractions could be identified; currently, 12 or more bands (i.e., stripes of ranging intensity on the test substance, see Fig. 10) can be distinguished on the pherograms. The number of investigations has also increased considerably [214] so that the results are becoming more significant all the time. Finally, instead of evaluating the colors via several experimental steps [214] they are nowadays measured directly by photometry. The most frequently used meth-

Table 40. Variation of some quality criteria of egg (%)

ods today are polyacrylamide gel electrophoresis (PAGE) and sodium dodecyl sulfate – PAGE (SDS – PAGE), which is used mainly for the analysis of whole eggs [213, 215, 216].

Figure 10. Schematic drawing of the bands on a pherogram of egg white separated by electrophoresis

In the following description of egg white proteins, the percentage of respective proteins in total egg white, the isoelectric point (IEP given as pH), and the molecular mass (M_r in daltons) are given for each case. This compilation is based on several publications (mainly [213] and [217]).

Ovalbumin, 54 wt %, IEP 4.5 – 4.8, M_r 46 000, is a glycoprotein that can be divided into three fractions A 1, A 2, and A 3 (fraction A 1 contains two phosphate units per molecule, A 2 one, and A 3 no phosphate unit per molecule). They differ in their electrophoretic mobility (1 < 3) and possess two, one, or no phosphate groups. This protein is stable up to 62 °C at pH 7. Further, it contains free sulfhydryl groups. On heating, S-ovalbumin is formed, which has a coagulation temperature of 92.5 °C [217].

Conalbumin, 12 – 13 wt %, IEP 6.05 – 6.6, M_r 76 600 – 86 000, is a glycoprotein that corresponds to serum albumin (ovotransferrin) of the chicken. It is heat labile and contributes to good foam formation, as can be seen in the extinction curves from pherograms of egg white from various types of poultry (see Fig. 11). In the case of water fowl (duck and goose) the conalbumin peak (VI) is specially small compared with that of land fowl (hen, turkey, and quail). Duck and goose egg whites are extremely difficult to foam.

Changes in the activity of conalbumin depend not only on temperature but also on pH. The aforementioned stabilizing additives (metal ions and organic acids, see 3.2.2) are added during pasteurization to maintain the functional activity of conalbumin.

Ovomucoid, 11 wt %, IEP 3.9 – 4.5, M_r 28 000, is a protein that contains disulfide bridges, oligosaccharides, and other carbohydrates. Due to its structure, this protein is very heat stable and is considered to be an enzyme inhibitor (trypsin inhibition).

Globulin, G 2: 4 wt %, IEP 5.5; G 3: 4 wt %, IEP 5.8, M_r of both 36 000 – 45 000. The two bands of globulin appear at positions 12 and 14 in the PAGE determination. Little is known about this protein. It seems to be heat stable and contributes to foam formation by increasing the volume of foam.

Lysozyme, 3.5 wt %, IEP 5.5, M_r 14 300 – 17 000 (also called muramidase), is often referred to as globulin G 1. It acts as a preservative and is responsible for the bactericidal effect of egg white. It forms complexes with other proteins (e.g., with ovalbumin, conalbumin, and ovomucin).

Ovomucin, 1.5 – 2.9 wt %, IEP 4.5 – 5.0, M_r 10 000, consists of glycoprotein chains (fibrils) that are linked through disulfide bonds. The gel structure of thick egg white is attributed to the

Figure 11. Extinction curves of various egg white samples after electrophoretic differentiation [214]

action of ovomucin, because only 1/4 of ovomucin is found in thin egg white.

The other electrophoretically identifiable proteins occur in egg white only in small amounts.

Ovoinhibitor, 0.1 – 0.5 wt %, IEP 5.1 – 5.2, M_r 46 000 – 49 000, is a moderately heat-stable protein that is stable up to 78 °C in the strongly acidic range. Trypsins are inactivated by ovoinhibitor.

Ovoglycoprotein, 0.5 – 1.0 wt %, IEP 3.9, M_r 24 400,contains hexose,glucosamine,and acetylmuramic acid among other compounds.

Flavoprotein, 0.8 wt %, IEP 3.9 – 4.1, M_r 32 000 – 36 000, or ovoflavoprotein binds riboflavin and is relatively heat stable.

Ovomacroglobulin, 0.5 wt %, IEP 4.5 – 4.7, M_r 760 000 – 900 000, the egg white protein with the highest molecular mass, was identified only in 1966 and is relatively heat stable.

Avidin, 0.05 wt %, IEP 9.5 – 10.0, M_r 68 300, is a basic protein that binds biotin. It is very heat stable and exerts an antibacterial effect.

3.2.2.2. Proteins in Egg Yolk

If egg yolk is centrifuged, the solids separate into yolk droplets (i.e., the plasma) and the granulose fraction [217]. Proteins are found in both fractions (see Fig. 12). Along with the readily water-soluble parts, the yolk contains 48.7 % water, 16.6 % protein and 32.6 % fat and carbohydrates. Most of the fat is bound to protein [217].

Plasma Proteins. The *low-density lipoproteins* (LDLs) are found in the plasma. Low-density lipoproteins account for 33.7 wt % of the yolk. The fat part of the lipoproteins consists of neutral fats and phospholipids. The protein part is involved mainly in emulsion ability; it is thermostable up to 75 °C and is active especially at the boundary layers.

Livetins, 5.5 wt % of the yolk, are present in three forms as water-soluble proteins:

α-Livetin, 1 %, IEP 4.8 – 5.0, M_r 80 000, serum protein
β-Livetin, 3 %, IEP 4.8 – 5.0, M_r 45 000, glycoprotein
γ-Livetin, 1.6 %, IEP 4.8 – 5.0, M_r 150 000, serum protein

The distribution of the three corresponds approximately to the ratio 2 : 5 : 3.

Figure 12. Composition of hen egg yolk [213]

Granulose Fraction. The granulose fraction (13 wt % of the yolk) contains mainly *high-density lipoproteins* (*HDL*s), which are called *lipovitellins.* The lipid part of these compounds (ca. 30 wt %) includes phospholipids and cholesterol. The glycoprotein part contains galactose, mannose, hexosamine, and sialic acid, among other substances; it is also involved in emulsion ability. α- and β-Lipovitellins differ in their mobility and in the proportion of phosphate bonds.

Phosvitin, approximately 2.1 wt % of the yolk, M_r 36 000 – 40 000, contains chiefly the amino acid serine. The phosphorus content is high (10 wt %). Two types of phosvitin occur:

α-Phosvitin, M_r 160 000 (15 – 22 wt % fat and 0.5 – 1.2 wt % protein)
β-Phosvitin, M_r 190 000 (17 – 22 wt % fat and 0.3 – 0.5 wt % protein).

Phosvitin exerts antioxidative effects [217], and binds iron and copper.

Emulsion Ability. Since the yolk proteins primarily determine the emulsion ability, attention must be drawn to the fact that emulsifiability can be evaluated in many ways. In general, definite amounts of fat, water, and yolk are mixed, in accordance with the "mayonnaise method," and the drainage is measured after a defined period of time [213].

3.2.3. Egg Products

In 1990, 35 160 t of egg products were traded in Germany in the following forms

49.5 %	whole egg (liquid/frozen)
17.1 %	egg yolk (liquid)
12.5 %	egg white (liquid/frozen)
6.5 %	whole egg (dried)
5.8 %	egg white (dried)
4.6 %	egg yolk (frozen)
2.2 %	egg rolls (precooked long egg)
1.8 %	egg yolk (dried)

The products are bought by food producers (bakeries, butchers, and meat processors) but also for the production of hair-care products, by the film industry (for coating film rolls), and tanneries.

Finished and semifinished products made from eggs include egg powder; liquids or pastes for making scrambled eggs with various ingredients (ham, mushrooms etc.); spreads as a supplement or substitute for butter, margarine, or cold meats; egg sausage in the form of solid egg white and yolk with the same cross-section as that of a sliced hardboiled egg; egg-based alcoholic and nonalcoholic beverages; and analogous low-cholesterol products.

Lysozyme is the most important substance isolated from egg white. It has a bactericidal effect and is used as a preservative in milk products, meat products, fresh fruit, and baby food [218].

3.3. Proteins from Blood

Blood is the most important byproduct of slaughtering it consists predominantly of protein and water, and is a valuable protein resource. The protein content in blood from domestic meat animals is equivalent to 6 – 7 % of the lean meat content in the carcass [219]. Because of the nutritionally valuable composition of blood and the large amounts of blood available from slaughterhouses, utilization of such blood seems reasonable. A requirement for blood that is utilized in human consumption is its hygienic collection.

3.3.1. Physical Properties of Blood

Blood consists of the intercellular substance, plasma, and suspended cells, which include erythrocytes (red cells), leukocytes (white cells), and thrombocytes (blood platelets). Cattle blood has a packed cell volume of 40 %; swine blood 42 %. Bovine blood has a density of 1.060 g/cm^3. The corresponding value for pig blood is1.040 g/cm^3. The freezing point of plasma is −0.5 to −0.6 °C. Blood is sometimes called "liquid meat" because its composition is similar to that of lean meat (Table 41) [220].

Table 41. Blood composition

	Cattle blood	Swine blood	Lean meat
Water, wt %	80.5	79.2	71.6
Protein, wt %	17.8	18.5	20.0
Fat, wt %	0.1	0.1	4.1
Carbohydrate, wt %	0.1	0.1	
Salts, wt %	0.9	1.0	1.1

3.3.2. Production

If blood is collected hygienically, it can be used for human consumption. Blood that is not hygienically recovered is converted into blood meal.

Collection of Edible Blood. Special precautions must be taken to minimize the contamination of blood with microorganisms during sticking of animals and subsequent storage of blood. The blood of healthy animals is normally sterile but can easily be contaminated in the slaughtering operation. There are two general categories of blood collection – closed and open systems. Closed systems have obvious advantages in preventing contamination. If good hygiene is maintained with cleaning-in-place installations, the microbiological quality of the blood should be less than 10^4 total plate- count of microorganisms per milliliter of blood [221].

The usual methods for blood collection involve the use of specially designed hollow knives discharging into cleanable receivers. The collected blood should be cooled as soon as possible to obtain preparations with low bacterial counts. Usually, blood from small numbers of animals is collected at a time and the result of veterinary inspection is awaited before the blood is mixed into a larger bulk.

Separation Process. Figure 13 shows the main fractions into which whole blood may be separated and Table 42 shows the composition of blood fractions. Unless anticoagulant is added, freshly drawn blood will coagulate or clot. Coagulation is prevented by the addition of an *anticoagulant solution* (sodium citrate or phosphate solution). When completely mixed with blood, this prevents the transformation of fibrinogen to fibrin and keeps the blood fluid. Addition of 3 g of trisodium citrate per kilogram of blood is sufficient as an anticoagulant. Increasing concentrations and amounts of trisodium citrate result in a linear increase of the plasma yield and a corresponding decrease of the protein concentration because the added citrate remains mainly in the plasma fraction [220].

Centrifugation of treated blood yields a red cell fraction (30 – 40 wt %) and a light-colored plasma fraction (60 – 70 wt %). The blood cells (thick blood) consist of cell wall material and proteinaceous material (almost entirely hemoglobin).

Continuous agitation also prevents coagulation by causing the fibrinogen to precipitate as fibrin. After separation, a red cell fraction and a serum fraction are obtained.

Blood Plasma Concentration and Preservation. After separation the plasma fraction can be stored at 4 °C for a maximum of 3 – 4 days. Often liquid or frozen plasma can be utilized "in-house" in meat food products. Alternatively, the

Table 42. Composition of blood fractions

	Blood	Blood plasma	Red cell concentrate	Dried plasma	Dried globin
Dry solids, wt %	18 – 20	7 – 9	28 – 37	96 – 97.5	96.5
Protein, wt %	16 – 18	6 – 9	28 – 38	70 – 96	91 – 95.4

$*$ Contents depend on quantity and type of anticoagulant used.

Figure 13. Separation of blood [222]

plasma is dried to remove water and thus to facilitate storage and also to reduce the costs of transportation.

When blood fractions are dried, great care must be taken to minimize denaturation. Plasma proteins begin to coagulate and denature at temperatures as low as 40 – 50 °C. Concentrating the blood plasma prior to drying is usually more economical. Concentration is performed by evaporation (falling-film evaporator or centri-term evaporator) or membrane filtration. The high salt content of plasma, which is a result of the added anticoagulant, can be lowered by ultrafiltration of the plasma. Normally the next step is spray drying of the concentrated plasma. Combination of ultrafiltration and spray drying gives a dried blood plasma protein isolate with 96.5 % protein and 2.5 % moisture [222].

Decolorization of Red Cell Concentrate (Thick Blood). When blood plasma is separated from the erythrocytes, the major portion (60–70 wt %) of the protein content remains in the erythrocyte fraction as hemoglobin. This hemoglobin imparts an undesirable dark red color to the product. Hemoglobin is often considered a very good catalyst for the oxidation of unsatured fatty acids; however, at high concentrations, it appears to have an inhibitory effect on fat oxidation [223]. The color can be lightened by emulsification of blood with fat and subsequent treatment of the blood – fat emulsion with a homogenizer [224]. The effect of this process is due to the light scattering of the dispersed tiny fat droplets. With regard to functional and nutritional properties of unaltered hemoglobin the emulsification process is advantageous but is not able to completely mask the heme pigment color when the product is cooked.

Several processes exist for *decolorizing* hemoglobin. The decolorized hemoglobin protein is generally referred to simply as "globin" in the literature. Traditionally, preparation of colorless globin is based on acid cleavage of hemoglobin and separation of globin from heme by organic solvents. Acidified cold acetone [225], methyl ethyl ketone [226], and ethanol – methanol [227] have been used. Tybor [228] converted hemoglobin to choleglobin by aerating a hemoglobin solution at pH 4 in the presence of ascorbic acid prior to the treatment with acidified acetone and developed a continuous process on a pilot scale. A serious problem with acetone-isolated globin is an off-flavor component that adheres to the protein molecule. All these extraction methods are not feasible economically. Alternatively, methods have been developed in which heme is removed from globin by adsorption on a medium (e.g., alginate) that is in contact with the acidified hemoglobin solution [229]. A chromatographic method has been presented in which heme and globin were separated by using a carboxymethyl cellulose (CMC) column in the acid pH range [230]. This method has been improved and developed further for industrial application [231].

Degradation of hemoglobin by proteolytic enzymes is an alternative method for avoiding dark pigmentation. The amino acids and peptides from the hydrolyzed protein can be separated from the heme by ultrafiltration or centrifugation. Olsen [232] and Hald-Christensen [233] used alcalase, whereas Drepper [234] used an acid proteinase. A degree of hydrolysis between 18 and 20 % is recommended, to give a yield of about 78 – 85 % [232]. Below a degree of 18 % hydrolysis the yield is unsatisfactory, and above 20 % a bitter taste becomes dominant in the product. Therefore a supplementary treatment with active carbon is recommended.

Hemoglobin can also be *lightened by bleaching* using hydrogen peroxide or ozone [235, 236]. The protein obtained is completely insoluble in water and has no functional properties.

Another method for decolorizing hemoglobin is acid-catalyzed *polymerization of released free heme.* Polymerized heme is separated by centrifugation and globin remains in solution. This polymerization is dependent on the concentration, type of hemoglobin derivative, pH, and temperature [237]. A second stage is necessary to remove residual heme [235, 237].

Blood Meal. Blood meal is a dark-brown granular product with 5 – 8 wt % moisture, produced by drying whole or thick blood. Blood is coagulated and then decanted and separated into blood meal and blood water. The blood meal is cooked, pressed to remove moisture, and dried or baked. The dried product is ground and used as feed or fertilizer.

To conserve the energy required for evaporation, newer techniques use a concentration process prior to drying the blood. The strained blood is preheated to 55 – 58 °C in a storage tank and pumped to a live steam coagulator where complete coagulation of blood proteins occurs. The coagulated blood is then dewatered by decanting, which removes 75 % of the water. The fine-crumb dewatered blood protein is then led to a cooker dryer for final drying (Fig. 14).

High temperatures and extended periods of drying decrease the nutritional value of blood meals. Blood can be dried by spray drying, freeze drying, ball drying, or roller drying. It should not be dried above 80 °C to maintain its digestibility. Spray drying is the most popular method of drying blood. Ball drying is accomplished with 20 – 30-mm balls, which are coated with a thin layer of blood and circulate through a drying chamber [239].

Figure 14. Blood meal production (Westfalia Separator Company [238])

3.3.3. Functional Properties of Blood Proteins

Blood is quite functional in food products primarily because of its albumin content [240]. On heating, albumin gels and retains fat and water. *Plasma,* whose protein content consists of 50 % albumin, is the best water and fat binder of the blood fractions. The firmness of plasma gel, which depends on concentration, temperature, pH, and ionic strength, is often used as an indicator of functionality. If drying is performed properly, plasma is highly soluble in water. The most unique functional property associated with plasma proteins is their exceptional binding ability when used in meat product formulations.

Blood proteins have excellent foaming capacity. For this reason, they can be used as a substitute for egg whites in the baking industry [240]. *Globin* has a high degree of surface activity as reflected in foaming properties and emulsifying activity. Table 43 summarizes the functional properties of blood plasma and globin.

Hemoglobin is a highly water-soluble protein with a high capacity to emulsify fats and develop stable foams. Removal of the heme group greatly reduces the stability of the globin protein molecule, and consequently the protein is much more sensitive to denaturing agents and heat. The solubility of globin is reduced in the pH range 6.5 – 8.5. The method of isolating globin significantly affects the functional properties of the final product. Acetone-treated globin prepared by the method of Tybor [228] possesses good water-binding capacity and emulsifying properties at pH ≤ 6 but lacks the gelation property [242]. Hayakawa [243] was the first to report that globin prepared by CMC – column chromatography forms a firm gel after being heated in the narrow pH range 5 – 6. He later used globin as a model protein for studying the process of gel formation [244].

Table 43. Functional properties of blood proteins [241]

Property	Plasma	Globin
Water solubility	good	good at pH < 6
Swelling with water	poor	very good
Viscosity	low	fair, high after heating
Emulsifying capacity	fair	good
Emulsifying stability	good, poorer with salt	good at pH < 6, better with salt
Foaming	good	very good
Gel formation	very good, sets $> 70\,^{\circ}$C, strength increased by salt	none, forms a thick cream

3.3.4. Nutritional Value of Blood Proteins

Blood is rich in heme iron, which is biologically the most available form of iron. The amino acid composition of whole blood plasma and globin proteins is shown in Table 44 and compared with the ideal values for a well-balanced diet as recommended by the FAO [241]. The low chemical scores of blood or globin indicate that they should be used to complement other proteins.

The amino acid profile of globin shows that its high lysine content and lack of isoleucine should make it an effective complement to certain vegetable proteins that have a high isoleucine content but are low in lysine.

3.3.5. Uses

Human Food. Blood proteins can be added to most food products. The most widely accepted food use of blood proteins is in meat products to increase protein levels and water-holding capacity. Because of its color the main use of *hemoglobin* is confined to products that traditionally have a dark color, such as black sausage, black pudding, blood breads, and blood cookies. Other possible uses for blood proteins are in the baking industry because of their foaming abilities and as nutritional supplements to any cereal food because of the high lysine content. *Blood plasma* is used in comminuted meat products. The addition of plasma to sausages of this type improves their water retention and reduces fat losses. *Globin* is used as a texture modifier and meat extender in ground-meat products [245].

Animal Feed. Blood meal is a basic feed product made from blood. Blood is also used in pet foods. Here its functional properties can be applied (e.g., in the formation of meatlike chunks).

Nonfood Uses. Blood can be used as nitrogenous fertilizer, glue, and fire-extinguishing foam [241].

Special fractions of animal blood processed under strict hygienic conditions are utilized in human medicine. Blood contains all the vital substances for human activity (i.e., proteins, mineral salts, vitamins, and enzymes). The enzyme orgotein (superoxide dismutase) is extracted from red cells. It is an antiinflammatory that detoxifies oxygen free radicals in the body. Purified thrombocytes are also being tested for their suitability in medicine. Bovine-derived blood substitutes have good possibilities for medicinal uses [246]. Apart from pharmaceuticals, animal blood fractions are used for biochemicals, diagnostics, and cosmetics (albumin, serum, plasma, hydrolysates) [246]. In the laboratory the most common uses of blood are as a nutrient for tissue culture media (vaccine production, monoclonal antibodies for mammalian tissue culture) and as a necessary ingredient in some agar cultures (transferrin, fibronectin, albumin).

3.3.6. Environmental and Legal Aspects

Blood is the main organic component in slaughterhouse wastewater [247] and the primary cause of slaughterhouse off-odors [248]. Slaughterhouses must collect the blood as completely as possible. Otherwise blood with a five-day biological oxygen demand (BOD_5) of 140 000 mg of O_2 per liter increases the organic loading of wastewater dramatically [247]. Even a BOD_5 of 250 000 mg of O_2 per liter of blood has been reported [249].

In most European countries, release of blood into wastewater is strictly forbidden. Nevertheless, nearly 15 % of the blood remains in the animal carcass and enters wastewater during the washing and splitting of the carcass [250].

3.3.7. Economic Aspects

Because of the high meat consumption and growing population, world meat production is increasing as are the resulting amounts of blood. Cattle and swine are the main sources of meat. The world meat production in 1990 [251] and calculated blood quantities are given in Table 45.

If the average yield of blood is 2.5 L per pig and 13 L per cow [250], this gives a protein source of 780 000 t/a, which is underutilized worldwide for religious, aesthetic, or social reasons. Scandinavian counries use about 70 % of the blood collected for human consumption; in Germany, only ca. 40 % is collected hygienically [253]. In Sweden, some 80 % of the available

Table 44. Essential amino acids in blood proteins (all figures in g per 100 g protein)

Assumptions used: [a] 304 kg/cattle and 82 kg/swine [252]. [b] 13 L/cattle and 2.5 L/swine [250]. [c] 18 % protein/L blood.

blood is said to be used directly as human food, 30 % of this as whole blood and 70 % after processing into plasma [241]; in Germany, up to 10 % of the blood plasma may be incorporated in cooked sausages.

More than 80 000 t of blood were collected and further processed into food products in the Soviet Union in 1970 and this amounted to only 21 % of all blood collected in that country. In the Soviet Union blood proteins are used as ingredient for various types of sausages and canned meat products.

The edible blood collected in the United States is not used in food products, but is fractionated to be applied for pharmaceutical purposes. Blood collected in accordance with the severe regulations issued by the Department of Agriculture (FSIS) may be used only in nonspecific meat products [240]. (Because of cultural taboos the meat industry in the United States does not utilize a valuable raw ingredient of abundant supply.)

4. Protein Hydrolysates and Derivatives

Protein hydrolysates are mixtures of peptides prepared by the chemically or enzymatically catalyzed hydrolysis of naturally occurring proteins. Protein hydrolysates are employed mainly in the food industry, in the technical sector, and as a raw material in cosmetics. Derivatives of protein hydrolysates are used widely in cosmetics and for technical applications. Total hydrolysates (see Section 3.1.5) and hydrolysates used in seasoning (e.g., soy sauce) [254] are not discussed here.

4.1. Protein Hydrolysates

4.1.1. Raw Materials

Being one of the fundamental building blocks of all living things, proteins are readily available in

nature. Examples of important protein sources for hydrolysates with technical applications are

1) **Animal Sources.** Slaughterhouse offal (skin, hair, blood, and nuchal ligament), milk, meat, fish, egg, silk, leather
2) **Plant Sources.** Press cakes from processing of oil seeds (soybean, cotton, almond, sunflower), protein from wheat, rice, potato, and peas

Some protein raw materials are available in different stages of enrichment (e.g., in the case of soybean as meal, concentrate, and isolate). The selection of a raw material depends on the particular application of the protein hydrolysate, the availability, and the cost of the protein.

Figure 15. Flow-sheet of the partial hydrolysis of proteins

4.1.2. Production Processes

In principle, proteins can be partially hydrolyzed by using the following processes:

1) Chemical hydrolysis
   Acid catalyzed
   Alkali catalyzed
2) Enzymatic hydrolysis

The general flow sheet for the partial hydrolysis of proteins is presented in Figure 15.

Raw Material Preparation. Depending on the quality of the raw material and the intended application of the protein hydrolysate, preparation consists of measures to reduce ash content, improve odor and color, and support the subsequent hydrolysis (oxidative or reductive pretreatment).

Chemical Hydrolysis. Chemical hydrolysis can be either acid or alkali catalyzed. In the case of acid hydrolysis, sulfuric or hydrochloric acids are mainly used, whereas $Ca(OH)_2$ or MgO is chiefly employed in alkaline cleavage.

The reaction is performed at 80 – 100 °C, and pH < 1 or > 12. The duration of hydrolysis is 6 – 18 h. Yields of at least 80 %, based on nitrogen, are obtained.

Enzymatic Hydrolysis. Enzymatic hydrolysis is performed with proteases that cleave interior peptide bonds of the polymer chains (endopeptidases). In addition, exopeptidases are used, which cleave single amino acids or dipeptides (from the terminal carboxyl and amino groups). The reaction proceeds under considerably gentler conditions at a maximum of 65 °C and a pH range of $\approx 2 - 11$. The duration of hydrolysis is 0.25 –12 h. Color and odor of the products obtained by enzymatic hydrolysis are often better than those obtained by chemical hydrolysis. Enzymatic hydrolysis has the advantage of potential stereochemical specificity. This permits controlled processes and fewer side reactions. The amount of chlorohydrins and salt in the hydrolysate is considered to be smaller than in hydrolysates prepared by acid hydrolysis. The nitrogen yields are at least 75 %.

Purification includes treatment with activated carbon for improvement of color and odor, precipitation of cations for reduction of the ash content [302], separation of bitter substances by adsorption, and fractionation of the hydrolysates by membranes.

In the production of *liquid protein hydrolysates,* the concentrates are preserved and clarified after an intermediate storage period of several days to a few weeks. Unpreserved protein hydrolysate powders can be obtained by spray drying of clarified and sterile filtered, unpreserved solutions.

4.1.3. Uses

4.1.3.1. Nutrition

Human Nutrition. An enzymatic or chemical hydrolysis step is associated with the production of many staple and luxury foods. Examples are the coagulation of casein by the enzyme rennin in cheese making (→ Cheese, Processed Cheese and Whey, Chap. 3.2.) and the decomposition of chill haze by the enzyme papain in the clarification of beer [255].

Apart from the protein hydrolysis inherent in many production processes, protein hydrolysates are deliberately added to foods to influence product properties. These hydrolysates are obtained mainly with enzymes that specifically alter the typical functional properties of proteins [303], such as

1) Solubility by alteration of the isoelectric point
2) Water-binding capacity
3) Whipping properties
4) Emulsifying capacity
5) Foam formation and stabilization
6) Gel formation
7) Fat and flavor binding

The nutritive value of the native protein is retained. The change in the functionality of the protein hydrolysate compared to that of the original protein depends on the enzyme used and the degree of hydrolysis [256]. Changes in the functional properties of soybean, bean, potato, and whey proteins are described in [257–260].

Protein hydrolysates frequently have a bitter taste that is caused, e.g., by the amino acid composition of the protein, the enzymes used, and the degree of hydrolysis. The bitterness restricts the use in foods [256, 261, 304].

As a result of the favorable physiological effects of protein hydrolysates, such as easy digestibility or low allergizing potential, acid-soluble soybean protein hydrolysates [*68607-88-5*] are added to dietetic drinks for athletes [262]. For the same reason, special hydrolysates are used to feed patients with gastroenterologic diseases [256, 263]. Protein hydrolysates are increasingly employed in treatment of, e.g., pancreatitis, short bowel syndrome, Crohn's disease, and food allergies [304, 305]. Hypoallergenic hydrolysates are employed in diets for babies [306, 307], who are allergic to whey proteins. The German legal regulations governing the use of proteins or protein hydrolysates in food are described in [264].

Animal Nutrition. Feed additives based on fish protein hydrolysates [*91079-91-3*] (see Section 3.1.5) serve as a source of nitrogen in milk replacers used for calf breeding [265]. Offal hydrolysates are used as animal feed [266].

4.1.3.2. Cosmetics

Protein hydrolysates are used in cosmetics because of the following properties:

Hydrophilicity
Amphoteric character
Pronounced buffering effect
High substantivity
Good film formation
Action as protective colloid
High water binding capacity

Hair Cosmetics. In hair dyeing, the addition of protein hydrolysates not only produces a more uniform adsorption of dyes on the keratin fibers, but also results in less loss of color during subsequent rinsing [267]. The film formation of protein hydrolysates causes an improvement in the luster of the hair and a better dry and wet combability [308], [309]. Protein hydrolysates in shampoos or hair repair products penetrate through the cuticula into the cortex of the hair and, thus, are capable of repairing split ends [268].

The negative effects of bleaching and cold waving processes on the hair can be reduced by the addition of protein hydrolysates [269]. Especially in the latter process, the increased alkali solubility of keratin can be lowered by the protective action of protein hydrolysates [270].

Skin Cosmetics. The use of skin cosmetics containing protein hydrolysates not only results in a soft skin but also improves the hydration state of the skin. These properties of protein hydrolysates are based on their hydrophilic and amphoteric character [271–273]. The rough skin phenomenon often observed when strongly degreasing surfactants, e.g., bulk surfactants, are

used can be drastically improved by the addition of protein hydrolysates because of their protective colloidal action [274].

Dermatological Effect. The most important property of protein hydrolysates is reduction of the irritant action of surfactants on the skin and the mucous membranes. These properties are based on both the amphoteric character and the substantivity of protein hydrolysates, and are especially pronounced in the case of collagen hydrolysates [*9015-54-7*] because of their nonexistent antigenic action [275,276].

4.1.3.3. Technology

Technical uses of protein hydrolysates are based on their foam producing, dispersive, and wetting properties. Keratin hydrolysates [*69430-36-0*] are used as basic protein foaming agents in the formulation of extinguishing foams [277]. Collagen hydrolysate can be employed in the production of waterproof concrete [278]. The overall prolongating influence exerted by protein hydrolysates on the setting time of gypsum and the specific effect of side chains of the amino acids they contain are described in [279]. Protein hydrolysates are used as textile auxiliaries in the mercerization of cotton [280], for wool protection in the dyeing of wool [281], and as dispersing agents in the formulation of dyes [282].

Soybean protein hydrolysates are used as binding agents for paper [283]. Protein hydrolysates, e.g., fish protein hydrolysate [*91079-91-3*] [310], have been proposed as sources of nitrogen for the nutrient media for microorganisms [284]. In the fermentation of carbohydrates to lactic acid, increases in yield are achieved by the addition of protein hydrolysates from wheat or fish protein [285,286].Collagen hydrolysates [*9015-54-7*] can be used as feeds and fertilizers [311].

4.2. Derivatives of Protein Hydrolysates

Raw Materials. The derivatives are directly synthesized from protein hydrolysates, which are produced as described in Section 4.1.2.

4.2.1. Acylated Products

The acylation of protein hydrolysates with acylating agents (see Table 46) can occur not only on the amino functions that are released by hydrolytic cleavage, but also on nucleophilic groups in the side chains of the protein hydrolysates ($-NH_2$, $-OH$, $-SH$) [312].

Synthesis. Hydrolysates are normally acylated in an aqueous alkaline medium according to Schotten – Baumann. In preparative applications, only acid chlorides are used as acylating agents (Fig. 16), esters have been of theoretical interest only until now [287]. The residue R^1 (see Table 46) of the acylating agent is a long-chain alkyl group in the case of fatty acids, or a tricyclic alkyl group in the case of resin acids (abietic acid).

Figure 16. Acylation of protein hydrolysates

Schotten – Baumann condensation proceeds at 60 °C (max.) under pH control. Intensive stirring is required because of the two immiscible liquid phases. Higher temperature favors the formation of soaps by hydrolysis of the acid chlorides [288].

The condensation product is normally purified for cosmetic applications. The acylation products are precipitated from the aqueous solution by lowering the pH (< 3) and are then washed to eliminate byproducts [289]. A water-soluble salt of the acylation product is reformed by subsequent neutralization with a base that is allowed in cosmetics, such as KOH or triethanolamine. The product can also be processed by drying to give an unpreserved powder.

Table 46. Derivatization scheme of protein hydrolysates *

Educt	Reagent	Product	Substituent
$R-NH_2$	$R^1-C(=O)-X$	$R-N(H)-C(=O)-R^1$	R^1 = alkyl-, cycloalkyl-
	$CH_2(O)-CH-CH_2-N^+(CH_3)_2-R^2$	$R-N(H)-CH_2-CH(OH)-CH_2-N^+(CH_3)_2-R^2$	$R^2 = -CH_3$, *n*-alkyl-
	$Cl-CH_2-CO_2^-Na^+$	$R-N(H)-CH_2-CO_2^-Na^+$	
$R-CO_2H$	R^3-OH	$R-C(=O)-OR^3$	R^3 = alkyl-

Applications. Protein hydrolysates acylated with long-chain fatty acids [*68920-65-0*] (R^1 = *n*-alkyl, see Table 46) or resin acids [*68918-77-4*], [*147993-64-4*] (R^1 = cycloalkyl) are anionic surfactants. They possess amphoteric character in their hydrophilic part and therefore show an especially low irritant potential compared to other surfactants [276]. Their foaming and washing ability is roughly comparable to that of bulk surfactants (e.g., alkylether sulfates). Therefore they are used in cosmetics as surfactants with excellent dermatological compatibility. Detailed experimental studies are available that compare the skin and mucous membrane compatibility of various surfactants with that of acylated protein hydrolysates [294–296, 313]. The skin compatibility of acylated protein hydrolysates can be improved by increasing the molecular mass of the peptide part of the acylated protein hydrolysate [290–293]. In the formulation of cosmetics or detergents, addition of small amounts of acylated protein hydrolysates to the more strongly irritating bulk surfactants results in a more than proportional improvement of their compatibility with skin and mucous membranes [275], [314].

As a special cosmetic effect the refatening of washed hair is significantly delayed by the addition of protein hydrolysate – abietic acid condensates [*68918-77-4*], [*147993-64-4*] (R^1 = cycloalkyl-, see Table 46) to shampoo [297, 298]. In anti-dandruff shampoos, protein hydrolysate – undecylenic acid condensate [*68951-92-8*] has a favorable effect [315].

Acylated protein hydrolysates are used as dispersing and complexing agents in the oxidative treatment of textile fibers [281].

4.2.2. Alkylated Products

The reactive groups of protein hydrolysates can be alkylated (see Table 46). Only reaction products with especially reactive alkylating reagents such as α-epoxides or their precursors or with chloroacetic acid are of technical importance.

Quats. In the production of "quats", chlorohydrins (e.g., 3-chloro-2-hydroxypropyl-*N,N,N*-dimethylalkylammonium chloride) are used as alkylating agents that are converted to the corresponding α-epoxides by the addition of alkali. These are the real alkylating agents. In this way, a group bearing a quaternary nitrogen is transferred to the protein hydrolysate, resulting in the formation of a cationic derivative that is positively charged over the entire pH range. The reaction is base catalyzed and proceeds in an aqueous medium at $\leq 60\,°C$.

Carboxymethylated Products. The reaction of protein hydrolysates with salts of chloroacetic acid gives carboxymethylated protein hydrolysates. This reaction is base catalyzed and is carried out at ca. 80 °C.

Applications. In comparison with the hydrolysates, the cationic protein hydrolysates exhibit a considerably stronger substantivity to hair

Table 47. Suppliers of protein hydrolysates and protein derivatives (selection)

	Firm	Protein raw materials used		Producers of protein		Use ∗
		Animal	Plant	Hydrolysates	Derivatives	
Europe	Croda	+	+	+	+	C
	Dt. Gelatine Fabriken (DGF)	+		+	+	C, F
	Diamalt	+	+	+		C, F
	Grünau/Henkel	+	+	+	+	C, F, T
	Sicit	+		+		T
	Seppic	+	+		+	C
	Kelisema		+	+		C
United States	Hormel	+		+		C
	Maybrook	+		+	+	C
	Brooks	+	+	+	+	C
	Sheffield	+		+		F
	Vegetech		+	+		C
Asia	Seiwa Kasei	+	+	+		C

∗ C = cosmetics, F = food/feed, T = technology.

or skin and are also absorbed on the surface of metals, glass, etc. For this reason, they are being increasingly used in cosmetics [299, 316]. In addition the molecules obtain a lipophilic character through the R^2 residue (see Table 46), which can be varied within wide limits. The molecules thus exhibit a weak surfactant action. Carboxymethylated protein hydrolysates are used as foam-free stabilizers for peroxide in the oxidative treatment of textile fibers.

4.2.3. Esters

Esterification of the carboxyl groups in protein hydrolysates and derivatives is possible. However, technical applications for these substances do not exist at present.

4.3. Product Properties

Commercially available protein hydrolysates and derivatives are powders having a light-beige to brown color and a characteristic odor. According to producers, the molecular masses are in the range of 400 to 100 000. Protein hydrolysates are very soluble in water and slightly soluble in polar organic solvents. Hydrolysates obtained by enzymatic degradation are optically active, products obtained by acid or alkaline hydrolysis are largely racemic.

4.4. Analysis

Protein hydrolysates and derivatives are characterized by determining the ash content, pH, amount of dry substance, total nitrogen, molecular mass distribution, and total microorganism count. Other product properties can be determined by using standard analytical methods for proteins [317].

4.5. Storage and Transportation

The austenitic stainless steels 1.4571 and 1.4439 are employed for the storage and transportation of protein hydrolysates and derivatives. The steel 1.4541 is only partially usable for hydrolysates and condensates because it is less resistant to corrosion. The stability to corrosion of the material used should be checked in each individual case because of the different salt concentrations of the commercial hydrolysates and derivatives.

The nonmetallic materials suitable for hydrolysates are low-density polyethylene, polypropylene, and polyester materials. Polyester and low-density polyethylene materials are suitable for protein – fatty acid condensates.

4.6. Economic Aspects

Reliable details about the amounts of protein hydrolysates and derivatives produced cannot be

given because the required statistics are unavailable. However, an estimated 40 000 t/a is produced worldwide for the main areas of application:

Cosmetics
Food and feeds
Technology

Selected suppliers of protein hydrolysates and protein derivatives are listed in Table 47.

4.7. Toxicology and Ecology

Toxicology. The American College of Toxicology has published conclusive reports on safety assessment of collagen hydrolysates [300] and acylated collagen hydrolysates [301, 312]. According to these reports, the two product classes are virtually nontoxic, minimally irritating to the rabbit eye, and not sensitizing in the guinea pig. These results are supported by decades of experience gained by producers and users and, according to present findings, can also be applied to other protein hydrolysates and their condensates.

Ecology. Protein hydrolysates and derivatives are based on renewable natural resources. This explains their biodegradability, which ranges from good to very good, and their easy metabolism. According to German law, protein hydrolysates belong to the water hazard class (WGK) 0; the condensates, to class 1; and the quats, to class 2.

1. Introduction

The term "psychopharmacological agents" refers to the wide variety of substances that affect the mind. These include not only agents that are used in clinical practice to alleviate or correct symptoms of psychiatric illnesses, but also drugs of abuse that are self-administered by humans for their subjective effects on the mood. The latter generally originate from natural preparations and have been known for a long time (e.g., caffeine, opiates, nicotine, cocaine). The

present article focuses on psychoactive drugs that are of therapeutic significance in psychiatry. Neurological medications such as hypnotics (→ Hypnotics), analgesics (→ Analgesics and Antipyretics), and sedatives (→ Sedatives) are treated in other chapters of this book, see also → Neuropharmacology.

The beginning of the modern era of psychopharmacology began in the early 1950s with the discovery of the antipsychotic properties of chlorpromazine. Since then, the therapeutic armament has successively benefited from the discovery of antidepressive drugs, anxiolytics or minor tranquilizers, and cognition enhancers that are believed to compensate for age-associated memory impairments and dementias. The psychopharmacological agents will be reviewed following this chronology.

Several classifications based on chemical structures, pharmacological properties, or clinical efficacy have been proposed for psychopharmacological agents, but none appears entirely satisfactory. Currently available drugs work symptomatologically, but do not alleviate the causes of the illnesses. The classification used here is based on the medical use of the psychopharmacological agents. The individual compounds are divided into categories with a common structural feature or a similar mode of action; they have been selected on the basis of their historical importance and their present world market. Several substances undergoing clinical development have also been reviewed. Lists of trade names are not exhaustive.

Some background of neurobiology has been included when necessary for the understanding of the mechanism of action of the drugs. Since the early 1970s knowledge of the central nervous system has become increasingly complicated by the discovery of brain processes with which psychoactive drugs may interact. A comprehensive account of the present state of the art in this field can be found elsewhere(→ Neuropharmacology).

2. Neuroleptics

Psychiatric disorders are generally divided into two classes. *Psychoses* (e.g., schizophrenia, mania, and depression) are severe diseases believed to result from the dysfunction of some brain processes. *Neuroses* refer to less debilitating affections related to exagerated reactions to life events otherwise considered as normal (e.g., anxiety).

The *neuroleptics,* also called *major tranquilizers* or *antipsychotics,* act on schizophrenia, the most prominent form of psychosis (1 % of the population is affected). Until the twentieth century, no treatment was available for those suffering from psychiatric disorders, particularly schizophrenia. Early medications are of little significance today (e.g., extracts of ergot or *Rauwolfia serpentina*). The observation of the antipsychotic properties of chlorpromazine and its introduction in clinical practice by Delay and Deniker in 1952 constituted a major breakthrough in the treatment of psychotic conditions [1]. This molecule, initially tested for its sedative properties, gave rise to the phenothiazine family (→ Phenothiazine and Derivatives). Several other families of neuroleptics were discovered soon after, including the thioxanthenes, butyrophenones, dibenzazepines, their piperazinyl derivatives and benzamides. The symptoms of schizophrenia include positive signs, such as psychomotor agitation, delusions, hallucinations, and negative symptoms including loss of social interaction and affective flattening. The observation that clinically effective neuroleptics have dopamine antagonist properties has led to the widely accepted hypothesis that an overactivity of this neurotransmitter system is involved in the disease [2–5]. Neuroleptics have a high affinity for D_1 and D_2 dopamine receptors, the D_2 receptors being of particular importance for their clinical effectiveness. The discovery of additional dopamine receptor subtypes may underlay the activity of several atypic neuroleptics [6]. Moreover, interaction with serotoninrgic processes in the brain may be involved in the action of certain antipsychotics. The experimental pharmacology of classical neuroleptics is characterized by their capacity to induce catalepsy and to antagonize the behavioral effects of dopaminomimetic agents (e.g., apomorphine). They also decrease body temperature, potentiate the activity of hypnotic and analgesic drugs, and impair conditioned avoidance responses. The dopamine antagonist properties are also related to the neurological side effects of these compounds (akathisia, dystonia, tardive dyskinesia). Other side effects arise from inter-

ference with dopaminergic systems in the hypothalamus or pituitary (e.g., increased prolactin levels). Neuroleptics can also be used against nausea and vomiting, and some are useful in the treatment of neuropsychiatric syndromes (e.g., Huntington's disease).

2.1. Phenothiazines

Phenothiazine itself was first synthesized by the end of the ninteenth century and used as a dye.

Its insecticidal and anthelmintic properties were described in the mid 1930s. The observation of the strong sedative properties of promethazine, a close analog with antihistaminic activity, prompted the synthesis of other centrally acting phenothiazines. This project resulted in the discovery of chlorpromazine, the prototype antipsychotic drug [1]. For a detailed description of phenothiazines, see → Phenothiazine and Derivatives.

The nitrogen atom of phenothiazine is substituted by aminoalkyl, piperidyl, or piperazinylalkyl side chains. The length of the side chain is critical: neuroleptic derivatives have three carbon atoms between the heterocyclic nitrogen and the tertiary nitrogen of the side chain. Compounds with only two carbon atoms show strong antihistaminic or anticholinergic activities.

The neuroleptic phenothiazines are usually synthesized by condensing a 2-substituted phenothiazine with halogenoalkylamines in the presence of a base:

2.1.1. 10-Aminoalkyl-Substituted Phenothiazines

The aliphatic side-chain derivatives are sedatives and act on cholinergic, histaminergic, dopaminergic, and adrenergic receptors [7].

$R = (CH_2)_3N(CH_3)_2$: promazine (X = H); chlorpromazine (X = Cl); triflupromazine ($X = CF_3$); acepromazine ($X = COCH_3$)

$R = (CH_2)CH(CH_3)CH_2N(CH_3)_2$: alimemazine (X = H); levomepromazine ($X = OCH_3$); cyamemazine (X = CN)

Promazine [*58-40-2*], 10-(3-dimethylaminopropyl)-10*H*-phenothiazine, $C_{17}H_{20}N_2S$, M_r 284.41, *bp* (0.04 kPa) 203 – 210 °C, for preparation see [8].

Trade Names. Atarzine (Saunders, Canada), Calmotal (SIT, Italy), Centractyl (Astra), Eliranol (Wyeth), Neuroplegil (Gentili, Italy), Prazine (Wyeth), Prozine (Hauck, USA), Sediston (Serono), Talofen (Pierrel, Italy), Tranquazine (Anthony, USA).

Chlorpromazine [*50-53-3*], 2-chloro-10-(3-dimethylaminopropyl)-10*H*-phenothiazine, $C_{17}H_{19}ClN_2S$, M_r 318.88, *bp* (0.106 kPa) 200 – 205 °C, for preparation see [9].

Trade Names. Elmarine (Marion, USA), Esmind (Otsuka, Japan), Largactil (Rhône-Poulenc), Megaphen (Bayer), Promactil (Wassermann, Spain), Promapar (Parke Davis), Promexin (Meiji, Japan), Propaphenin (Deutsches Hydrierwerk, Germany), Prozin (Lusofarmaco, Italy), Psychozine (Forest, USA), Thorazine (SKF).

Triflupromazine [*146-54-3*], 10-(3-dimethylaminopropyl)-2-trifluoromethyl-10*H*-phenothiazine, $C_{18}H_{19}F_3N_2S$, M_r 352.49, *bp* (0.053 kPa) 162 – 164 °C, for preparation see [10].

Trade Names. Psyquil (Squibb, France), Siquil (Squibb, Belgium), Vesprin (Squibb, Canada).

Acepromazine [*61-00-7*], 2-acetyl-10-(3-dimethylaminpropyl)-10*H*-phenothiazine, $C_{19}H_{22}N_2OS$, M_r 326.47, *bp* (0.066k Pa) 220–240 °C, for preparation see [11].

Trade Names. ACP C-VET (Arovet, Switzerland), Calmivet (Vetoquinol, France), Neurotranq (Alfasan, The Netherlands), Sedalin (Chassot, Switzerland).

Alimemazine [*84-96-8*],10-(3-dimethylamino-2-methylpropyl)-10*H*-phenothiazine, $C_{18}H_{22}N_2S$, M_r 298.44, *mp* 68 °C, for preparation see [12].

Trade Names. Panectyl (Specia, France), Spansule (Herbert, USA), Temaril (SKF), Théralène (Rhône-Poulenc), Vallergan (May & Baker).

Levomepromazine [*60-99-1*], 2-methoxy-10-(3-dimethylamino-2-methylpropyl)-10*H*-phenothiazine, $C_{19}H_{24}N_2OS$, M_r 328.46, *mp* 190 °C, for preparation see [12].

Trade Names. Levomezine (Toho, Japan), Levomeprome (Lederle), Levonormal (Sawai, Japan), Minozinan (Specia), Neurocil (Bayer), Nozinan (Specia), Procrazine (Toyo Pharmar, Japan), Sofmin (Dainippon, Japan), Veractil (Rhône-Poulenc), Sinogan (Rhone, Spain).

Cyamemazine [*3546-03-0*], 2-cyano-10-(3-dimethylamino-2-methylpropyl)-10*H*-phenothiazine, $C_{19}H_{21}N_3S$, M_r 323.47, *mp* 89–96 °C, for preparation see [13].

Trade Name. Tercian (Théraplix, France).

2.1.2. 10-Piperidylalkyl-Substituted Phenothiazines

The phenothiazines containing piperidyl side chains have a relatively high neuroleptic potency; some induce less extrapyramidal side effects than chlorpromazine. They show anticholinergic and adrenolytic activity.

2.1.2.1. Piperidylethyl-Substituted Phenothiazines

Thioridazine [*50-52-2*], 2-methylmercapto-10-[2-(1-methyl-2-piperidyl)ethyl]-10*H*-pheno-thiazine, $C_{21}H_{26}N_2S_2$, M_r 370.56, *mp* 72–74 °C, for preparation see [14].

Trade Names. Mallorol, Meleril, Mellaril, Melleril (Sandoz), Novoridazine (Novopharm, Canada), Orsanil (Orion, Finland), Ridazin (Taro, Israel), Stalleril (Pharmacal, Finland), Thioril (ICN, Canada).

Mesoridazine [*5588-33-0*], 2-methylmercapto-10-[2-(1-methyl-2-piperidyl)ethyl]-10*H*-phenothiazine-2-oxide, $C_{21}H_{26}N_2OS_2$, M_r 386.59, *mp* 115–120 °C, for preparation see [15].

Trade Names. Calodal (Heyden, Germany), Lidanil (Sandoz), Serentil (Sandoz).

Sulforidazine [*14759-06-9*], 2-methylsulfonyl-10-[2-(1-methyl-2-piperidyl)ethyl]-10*H*-phenothiazine, $C_{21}H_{26}N_2O_2S_2$, M_r 402.57, *mp* 121–123 °C, for preparation see [16].

Trade Name. Inofal (Sandoz, Germany).

2.1.2.2. Piperidinopropyl-Substituted Phenothiazines

Pipamazine	X = Cl	R = N–CONH$_2$
Pericyazine	X = CN	R = N–OH
Piperacetazine	X = COCH$_3$	R = N–(CH$_2$)$_2$OH
Pipotiazine	X = SO$_2$N(CH$_3$)$_2$	R = N–(CH$_2$)$_2$OH
Spiclomazine	X = Cl	R = N–S–N–O, H

Pipamazine [*84-04-8*], 10-[3-(4-carbamoylpiperidino)propyl]-2-chloro-10*H*-phenothiazine, $C_{21}H_{24}ClN_3OS$, M_r 401.97, *mp* 139 °C, for preparation see [17]. Pipamazine is also used as an antiemetic.

Trade Names. Nometine (Searle), Nansidol, Mornitine.

Pericyazine [*2622-26-6*], 2-cyano-10-[3-(4-hydroxypiperidino)propyl]-10*H*-phenothiazine, $C_{21}H_{23}N_3OS$, M_r 365.50, *mp* 116–117 °C, for preparation see [18].

Trade Names. Amplan (Taisho, Japan), Aolept (Bayer), Apamin (Yoshitomi, Japan), Nemactil (Specia), Neulactil (May & Baker), Neuleptil (Rhône-Poulenc).

Piperacetazine [*3819-00-9*], 2-acetyl-10-[3-[4-(2-hydroxyethyl)piperidino]propyl]-10*H*-phenothiazine, $C_{24}H_{30}N_2O_2S$, M_r 410.59, *mp* 100–110 °C, for preparation see [19].

Trade Name. Quide (Merrell Dow).

Pipotiazine [*39860-99-6*], 10-{3-[4-(2-hydroxyethyl)piperidino]propyl}-*N,N*-dimethyl-10*H*-phenothiazine-2-sulfonamide, $C_{24}H_{33}N_3O_3S_2$, M_r 475.66, *mp* 58–59 °C, for preparation see [20].

Trade Names. Piportil (Rhodia, Brazil), Piportil Depot (May & Baker), Piportil Longum (Specia), Piportyl (Rhône-Poulenc).

Spiclomazine [*24527-27-3*], 8-[3-(2-chloro-10*H*-phenothiazin-10-yl)propyl]-1-thia-4,8-diazaspirol[4, 5]decan-3-one, $C_{22}H_{24}ClN_3OS_2$, M_r 446.02, *mp* 154–156 °C, for preparation see [21].

Trade Name. Diceplon (Yoshitomi, Japan).

2.1.3. 1-Piperazinylpropyl-Substituted Phenothiazines

The piperazine derivatives are the most potent phenothiazine neuroleptics. They have only mild sedative effects, induce strong extrapyramidal side effects, and have a lower propensity for inducing autonomic side effects due to the lack of high-affinity binding to cholinergic and adrenergic receptors.

Perazine [*84-97-9*], 10-[3-(4-methyl-1-piperazinyl)propyl]-10*H*-phenothiazine, $C_{20}H_{25}N_3S$, M_r 339.49, *mp* 51–53 °C, for preparation see [22].

Trade Name. Taxilan (Promonta).

Perazine	X = H	R = CH$_3$
Prochlorperazine	X = Cl	R = CH$_3$
Trifluoperazine	X = CF$_3$	R = CH$_3$
Thioproperazine	X = SO$_2$N(CH$_3$)$_2$	R = CH$_3$
Butaperazine	X = CO(CH$_2$)$_2$CH$_3$	R = CH$_3$
Perphenazine	X = Cl	R = CH$_2$CH$_2$OH
Fluphenazine	X = CF$_3$	R = CH$_2$CH$_2$OH
Acetophenazine	X = COCH$_3$	R = CH$_2$CH$_2$OH
Carphenazine	X = COCH$_2$CH$_3$	R = CH$_2$CH$_2$OH

Prochlorperazine [*58-38-8*], 2-chloro-10-[3-(4-methyl-1-piperazinyl)propyl]-10*H*-phenothi-azine, $C_{20}H_{24}ClN_3S$, M_r 373.94, *mp* 228 °C (dimaleate), for preparation see [23].

Trade Names. Anti-Naus (Protea, Australia), Bucastem (Reckitt & Colman, UK), Compazine (SKF), Nipodal (Bayer), Normalmin (Sawai, Japan), Stemetil (Farmitalia, Italy), Tementil (Specia), Vertigon (SKF).

Trifluoperazine [*117-89-5*], 2-trifluoromethyl-10-[3-(4-methyl-1-piperazinyl)propyl]-10*H*-phenothiazine, $C_{21}H_{24}F_3N_3S$, M_r 407.49, *bp* (0.08 kPa) 202 – 210 °C, for preparation see [24].

Trade Names. Eskazine (SKF), Jatroneural (Röhm Pharma, Germany), Modalina (Maggioni-Winthrop, Italy), Novolurazine (Novapharm, Canada), Pentazine (Pentagone, Canada), Solazine (Horner, Canada), Stelazine (SKF), Telazin (SKF), Terfluzine (Theraplix, France), Trifluoper-Ez-Ets (Barlowe Cote, Canada).

Thioproperazine [*316-81-4*], 10-[3-(4-methyl-1-piperazinyl)propyl]-*N,N*-dimethyl-10*H*-phenothiazine-2-sulfonamide, $C_{22}H_{30}N_4O_2S_2$, M_r 446.64, *mp* 140 °C, for preparation see [25].

Trade Names. Majeptil (Specia, France), Mayeptil (Rhodia, Argentina).

Butaperazine [*653-03-2*], 2-butyryl-10-[3-(4-methyl-1-piperazinyl)propyl]-10*H*-phenothi-azine, $C_{24}H_{31}N_3OS$, M_r 409.60, *bp* (0.006 kPa) 270 – 280 °C, for preparation see [26].

Trade Names. Randolectil (Bayer, Argentina), Repoise (Robins, USA).

Perphenazine [*58-39-9*],2-chloro-10-{3-[4-(2-hydroxyethyl)-1-piperazinyl]propyl}-10*H*-phe-nothiazine, $C_{21}H_{21}ClN_3OS$, M_r 403.97, *mp* 94 –100 °C, for preparation see [27].

Trade Names. Decetan (Merck), Etaperazin (Medexport, IEC), Fentazin (Allen & Hanburys, UK), F-Mon (Kuroishi, Japan), Phenazine (ICN, Canada), Trilafon (Schering), Trilifan (Cétrane, France).

Metofenazate [*388-51-2*], $C_{31}H_{36}ClN_3O_5S$, M_r 598.18, *mp* 102 – 107 °C, is the 3,4,5-trimethoxybenzoate of perphenazine; for preparation see [28].

Trade Name. Frenolon (Egis, Hungary).

Thiopropazate [*84-06-0*], $C_{23}H_{28}ClN_3O_2S$, M_r 446.00, *bp* (0.1 kPa) 214 – 218 °C, is the acetate of perphenazine; for preparation see [29].

Trade Names. Dartal, Dartalan (Searle).

Fluphenazine [*69-23-8*], 10-{3-[4-(2-hydroxyethyl)-1-piperazinyl]propyl}-2-trifluoromethyl-10*H*-phenothiazine, $C_{22}H_{26}F_3N_3OS$, M_r 437.52, *bp* (0.066 kPa) 268 – 274 °C, for preparation see [30].

Trade Names. Anatensol, Calmansial, Dapotum, Moditen, Prolixin (Squibb); Eutimox (Soc. Gen. de Pharmacia, Switzerland); Lyorodin (Deutsches Hydrierwerk, Germany); Omca (Heyden, Germany); Pacinol, Permitil, Trancin (Schering); Siqualine (Iquinosa, Spain).

Acetophenazine [*2751-68-0*], 2-acetyl-10-{3-[4-(2-hydroxyethyl)-1-piperazinyl]propyl}-10*H*-phenothiazine, $C_{23}H_{29}N_3O_2S$, M_r 411.57, *mp* 167 – 168 °C, for preparation see [31].

Trade Name. Tindal (Schering, UK).

Carphenazine [*2622-30-22*], 10-[3-[4-(2-hydroxyethyl)-1-piperazinyl]propyl]-2-propionyl-10*H*-phenothiazine, $C_{24}H_{31}N_3O_2S$, M_r 425.6, *mp* 175 – 177 °C, for preparation see [32]

Trade Name. Proketazine (Wyeth, USA).

Two other compounds are analogous to the phenothiazines described above:

Homofenazine [3833-99-6], 10-{3-[hexahydro-4-(2-hydroxyethyl)-1,4-diazepine-1-yl]propyl}-2-trifluoromethyl-10*H*-phenothiazine, $C_{23}H_{28}F_3N_3OS$, M_r451.52, *bp* (0.133 kPa) 230 – 240 °C, is homologous to fluphenazine; for preparation see [33].

Trade Name. Pasaden (Homburg).

Prothipendyl [*1225-65-6*], 10-(3-dimethylaminopropyl)-10*H*-pyrido[3,2-*b*][1, 4]benzothiazine, $C_{16}H_{19}N_3S$,M_r285.42, *bp* (0.093 kPa) 217 –219 °C, for preparation see [34], is analogous to promazine (azaphenothiazine) with general properties similar to those of chlorpromazine.

Trade Names. Dominal (Astra, Germany), Tolnate (SKF, UK).

2.2. Thioxanthenes

The thioxanthene neuroleptics are chemically and pharmacologically related to the phenothiazines. Activity resides with the *cis* isomers. The aminoalkyl and piperazinylalkyl side chains are similar to those of the phenothiazines, producing comparable potencies and side effects. The thioxanthenes are prepared by condensing the tricyclic ketone with the Grignard reagent of the desired aminoalkyl chain. The resulting alcohol is then dehydrated in an acidic medium.

Chlorprothixene [*113-59-7*], 2-chloro-9-(3-dimethylaminopropylidene)-9*H*-thioxanthene, $C_{18}H_{18}ClNS$, M_r 315.86, *mp* 97 – 98 °C, for preparation see [35].

Trade Names. Cloxan (Orion, Finland); Paxyl (Ikepharm); Tactaran (Roche), Taractan, Tarasan, Taratan (Roche); Truxal, Truxaletten (Lundbeck).

Thiothixene [*3313-26-6*], *cis*-9-[3-(4-methyl-piperazinyl)propylidene]-*N*,*N*-dimethyl-9*H*- thioxanthene-2-sulfonamide $C_{23}H_{29}N_3O_2S_2$, M_r 443.63, *mp* 147 – 149 °C, for preparation see [36].

Trade Names. Navane, Navaron, Orbinamon (Pfizer).

Flupentixol [*2709-56-0*], 9-{3-[4-(2-hydroxyethyl)-1-piperazinyl]propylidene}-2-trifluoromethyl-9*H*-thioxanthene, $C_{23}H_{25}F_3N_2OS$, M_r 434.54, *mp* 236 – 240 °C, is prepared with the alcoholic function protected as a benzyl ether. This protection is removed by catalytic hydrogenation at the end of the synthesis [37].

Trade Names. Depixol, Fluanxol (Lundbeck, Denmark), Emergil (Labaz), Metamin (Takeda, Japan), Phrenixol (Ikepharm, Israel), Siplarol (Farmitalia, Italy).

Clopenthixol [*982-24-1*], 2-chloro-9-{3-[4-(2-hydroxyethyl)-1-piperazinyl]propylidene}-9*H*-thioxanthene, $C_{22}H_{25}ClN_2OS$, M_r 400.99, *mp* 250–260 °C (dihydrochloride), for preparation see [38].

Trade Names. Ciatyl, Sordena, Sordinol (Kefalas).

Zuclopenthixol [*53772-83-1*], $C_{22}H_{25}ClN_2OS$, M_r 400.99, *mp* 84–85 °C, is the *cis* isomer of clopenthixol [38].

Trade Names. Cisodinol, Clopixol (Lundbeck, Denmark); Sedanxol (Tropon, Germany).

2.3. Piperidinobutyrophenones

The piperidinobutyrophenones are the most potent neuroleptics (benperidol, trifluperidol). They have a higher binding selectivity for D_2 than for D_1 receptors, lack affinity for cholinergic receptors, and show less sedative side effects [7]. The butyrophenones are prepared by condensing the relevant piperidine derivative with 4-chloro-1-(4-fluorophenyl)-1-butanone.

4-Chloro-1-(4-fluorophenyl)-1-butanone

Haloperidol [*52-86-8*], 4-[4-(4-chlorophenyl)-4-hydroxypiperidino]-4′-fluorobutyrophenone, $C_{21}H_{23}ClFNO_2$, M_r 375.88, *mp* 148–149 °C, for preparation see [39]. Haloperidol is also used in the management of Gilles de la Tourette's syndrome.

Trade Names. Brotopon (Pfizer), Duraperidol (Durachemie, Germany), Haldol (Janssen), Halojust (Horita, Japan), Halopidol (Johnson & Johnson), Halosten (Shionogi, Japan), Keselan (Sumitomo, Japan), Linton (Yoshitomi, Japan), Novoperidol (Novopharm, Canada), Selezyme (Sawai, Japan), Serenace (Searle).

Bromperidol [*10457-90-6*], 4-[4-(4-bromophenyl)-4-hydroxypiperidino]-4′-fluorobutyrophenone, $C_{21}H_{23}BrFNO_2$, M_r 420.33, *mp* 155–158 °C [39].

Trade Names. Azuren, Bromidol, Impromen (Janssen), Tesoprel (Organon, Germany).

Moperone [*3871-82-7*], 4′-fluoro-4-[4-hydroxy-4-(4-methylphenyl)piperidino]butyrophenone, $C_{22}H_{26}FNO_2$, M_r 355.46, *mp* 118–119 °C, for preparation see [40].

Trade Names. Luvatren, Luvatrena, Luvatrene (Cilag-Chemie).

Fluanisone [*1480-19-9*], 4′-fluoro-4-[4-(2-methoxyphenyl)-1-piperazinyl]butyrophenone, $C_{21}H_{25}FN_2O_2$, M_r 356.45, *mp* 205 °C, for preparation see [41].

Trade Name. Sédaland (Delalande, France).

Trifluperidol [*749-13-3*], 4′-fluoro-4-[4-hydroxy-4-(3-trifluoromethylphenyl)piperidino]-butyrophenone, $C_{22}H_{23}F_4NO_2$, M_r 409.43, *mp* 200 – 201 °C, for preparation see [42].

Trade Name. Triperidol (Lagap, UK).

Pipamperone [*1893-33-0*], 4-[(4-carbamoyl-4-piperidino)-4′-fluorobutyrophenone, $C_{21}H_{30}FN_3O_2$, M_r 375.49, *mp* 124 – 126 °C (dihydrochloride), for preparation see [43].

Trade Names. Dipiperal (Johnson & Johnson), Dipiperon (Janssen, France), Piperonil (Lusofarmaco, Italy), Propitan (Esai, Japan).

Spiperone [*749-02-0*], 8-[3-(4-fluorobenzoylpropyl]-4-oxo-1-phenyl-1,3,8-triazaspiro[4,5]-decane, $C_{23}H_{26}FN_3O_2$, M_r 395.48, *mp* 190 – 194 °C, for preparation see [44].

Trade Name. Spiropitan (Japan).

Benperidol [*2062-84-2*], 1-{1-[3-(4-fluorobenzoyl)propyl]-4-piperidyl}-2-benzimidazolinone, $C_{22}H_{24}FN_3O_2$, M_r 381.45, *mp* 170 – 172 °C, for preparation see [45].

Trade Names. Anquil (Janssen, UK), Frenactil (Janssen, Belgium), Clianimon (Tropon, Germany), Psicoben (Ravizza, Italy).

Timiperone [*57648-21-2*], 1-{1-[3-(4-fluorobenzoyl)propyl]-4-piperidyl}-2-mercaptobenzimidazole, $C_{22}H_{24}FN_3OS$, M_r 397.5, *mp* 201 –203 °C, for preparation see [46].

Trade Name. Tolopelon (Daichi, Japan).

Droperidol [*548-73-2*], 1-{1-[3-(4-fluorobenzoyl)propyl]-1,2,3,6-tetrahydro-4-pyridyl}-2-benz-imidazolinone, $C_{22}H_{22}FN_3O_2$, M_r 379.4, *mp* 145 – 146 °C, for preparation see [47]. Droperidol shows a long duration of action. It is used in conjunction with an analgesic (e.g., fentanyl) to induce neuroleptanalgesia in anesthesiology.

Trade Names. Dehydrobenperidol, Droleptan (Janssen), Inapsine (McNeil, USA), Sintodian (Farmitalia Carlo Erba).

Melperone [*3575-80-2*], 4′-fluoro-4-(4-methylpiperidino)butyrophenone, $C_{16}H_{22}FNO$, M_r 263.37, *mp* 209 – 211 °C (hydrochloride), for preparation see [48]. Unlike the other butyrophenones, melperone shows only weak affinity for the dopamine receptors. It seems to act

through the serotonin 5-HT_2 receptor for serotonin (5-hydroxytryptamine, 5-HT). Melperone is one of the noncataleptogenic neuroleptics with a low tendency for inducing extrapyramidal side effects.

Trade Names. Buronil (Ferrosan, Italy), Eunerpan (Nordmark, Germany).

2.4. Diphenylbutylpiperidines

The diphenylbutylpiperidines are structurally related to the piperidinobutyrophenones. They are relatively selective for the D_2 receptors and do not interact with histaminergic receptors [7]. In addition, these neuroleptics are able to block voltage-dependent calcium channels [49].

Fluspirilene [*1841-19-6*], 8-[4,4-bis(4-fluorophenyl)butyl]-1-phenyl-1,3,8-triazaspiro[4.5]-decan-4-one, $C_{29}H_{31}F_2N_3O$, M_r 475.59, *mp* 187 – 190 °C is prepared by condensing a spirobicyclic amine with the relevant brominated diphenylbutane derivative. The spiro compound is prepared from cyclohexanone via an aminonitrile (Strecker synthesis) [50].

Fluspirilene bears the same side chain as spiperone (see Section 2.3). The deep intramuscular injection of a microcrystalline suspension of fluspirilene results in a long duration of action (ca. one week).

Trade Names. Imap (Janssen), Redeptin (SKF, UK).

Penfluridol [*26864-56-2*], 1-[4,4-bis(4-fluorophenyl)butyl]-4-(4-chloro-3-trifluoromethylphenyl)-4-hydroxypiperidine, $C_{28}H_{27}ClF_5NO$, M_r 523.99, *mp* 105 – 107 °C, is obtained by reducing the ketone of 3-(4-fluorobenzoyl)propionic acid into a lactone. Alkylation of fluorobenzene with this lactone under Friedel – Crafts conditions yields a diarylbutyric acid, which is converted into an amide and reduced to the amine; for details of synthesis see [51].

Trade Names. Cyperon (Esteve, Spain), Fluidol (Janssen), Longoran (Isis, Yugoslavia), Micefal (Spofa, Czechoslovakia).

Pimozide [*2062-78-4*], 1-{1-[4,4-bis(4-fluorophenyl)butyl]-4-piperidinyl}-2-benzimidazolinone, $C_{28}H_{29}F_2N_3O$, M_r 461.56, *mp* 214 – 218 °C. Ring opening of diphenylcyclopropylcarbinol gives a homoallylic chloride

which is hydrogenated and then condensed with the relevant benzimidazolinone derivative [52]. The side chain is identical to that of benperidol (see page 10).

Pimozide is used for the treatment of acute and chronic schizophrenia and also in management of Gilles de la Tourette's syndrome.

Trade Names. Antalon (Arzneimittelwerk Dresden, Germany), Opiran (Roussel, France), Oralep (Abic, Israel), Orap (Janssen), Pimotid (Medica, Finland), Pirium (Janssen)

2.5. Dibenzazepines and Analogues

This class of drugs includes tricyclic compounds with seven-membered central rings. Clozapine was the first neuroleptic that seldom showed extrapyramidal side effects and was therefore termed an "atypical" neuroleptic.

Two subclasses can be distinguished:

1) The seven-membered ring is an azepine having a piperidinoalkyl chain on its nitrogen atom (carpipramine and clocapramine)
2) The basic substituent (a *N*-methylpiperazine) is attached to the imino bridge

Structural variations in this series of compounds led to the development of classical neuroleptics (clothiapine, loxapine, and clozapine) and hypnotics (perlapine).

2.5.1. Dibenzazepines

The dibenzazepine derivatives are prepared by the following general method: the tricyclic nitrogen atom is alkylated with a 1,3-dihalogenated propane, the resulting monohalogeno compound is then condensed with the piperidine derivative:

Carpipramine [*5942-95-0*], 5-[3-(4-piperidino-4- carbamoylpiperidino)propyl]-10,11-dihydro-5*H*-dibenz[*b,f*]azepine, $C_{28}H_{38}N_4O$, M_r 446.64, *mp* 260 °C, for preparation see [53]. The compound is a 5-HT_2 antagonist. This could explain its clinical efficacy in symptoms like asthenia, anxiety, and social withdrawal.

Trade Names. Defekton (Yoshitomi, Japan), Prazinil (Fournier, France).

Clocapramine [*47739-98-0*], 5-{[3-(4-carbamoyl-4-piperidino]propyl}-3-chloro-10,11-dihydro-5*H*-dibenz[*b,f*]azepine dihydrochloride monohydrate, $C_{28}H_{41}Cl_3N_4O_2$, M_r 572.0, *mp* 267 °C is a chlorinated derivative of carpipramine with a bitter taste; for preparation see [53].

Trade Name. Clofekton (Yoshitomi, Japan).

2.5.2. Piperazinyl Derivatives

Dibenzazepine analogues are prepared by two main routes (Fig. 1). In the first one, the lactam function of the tricycle is activated as an imino chloride (A) or a thioether (B), which is then condensed with *N*-methyl piperazine. In the second

Figure 1. Synthesis of benzazepine analogues

route, the imino bridge of the tricycle is formed by dehydration of an urea function (C) or condensation of an amine and an amide function (D).

Clothiapine [*2058-52-8*], 2-chloro-11-(4-methyl-1-piperazinyl)-dibenzo[*b,f*][1, 4]thiazepine, $C_{18}H_{18}ClN_3S$, M_r 343.89, *mp* 118–120 °C, for preparation see [54].

Trade Names. Deliton (Dainippon, Japan), Entumine, Etomine, Etumina, Etumine (Sandoz Wander).

Clozapine [*5786-21-0*], 8-chloro-11-(4-methyl-1-piperazinyl)-5*H*-dibenzo[*b, e*][1, 4]diazepine, $C_{18}H_{19}ClN_4$, M_r 326.83, *mp* 183–184 °C, for preparation see [55].

Despite severe hematologic side effects (agranulocytosis), this compound is used to treat otherwise irresponsive patients. Clozapine has one order of magnitude higher affinity for the D_4 receptors than for D_2 receptors [56].

Trade Names. Alemoxan (Arzneimittelwerk Dresden, Germany), Clozaril (Sandoz Wander, UK), Leponex (Sandoz Wander).

Loxapine [*1977-10-2*], 2-chloro-11-(4-methyl-1-piperazinyl)-dibenz[*b,f*][1, 4]oxazepine, $C_{18}H_{18}ClN_3O$, M_r 327.81, *mp* 109–110 °C, for preparation see [57].

Trade Names. Daxolin (Dome, USA); Desconex (Lafarquim, Spain); Loxapac, Loxitane (Lederle).

2.6. Benzamides

The benzamide neuroleptics are selective blockers of D_2 receptors and are therefore free of the side effects arising from interactions with other receptors. Sulpiride, the most important member of this class, was recognized as an "atypical" neuroleptic [58]. It exhibits a specific action on the mesolimbic dopamine system [59].

Sulpiride [*15676-16-1*], *N*-[(1-ethyl-2-pyrrolidinyl)methyl]-2-methoxy-5-sulfamoylbenzamide, $C_{15}H_{23}N_3O_4S$, M_r 341.43, *mp* 175 – 182 °C, is prepared by reaction of 2-aminomethyl-1-ethyl-pyrrolidine with phosphorus trichloride, followed by the condensation of the intermediate with 5-sulfamoyl-2-methoxybenzoic acid [60].

Trade Names. Abilit (Sumitomo, Japan), Aiglonyl (Fu-mouze, France), Arminol (Krewel, Germany), Azugastan (Kobayashi, Japan), Betamac, Dixibon (Sandoz, Switzerland), Dobren (Ravizza, Italy), Dogmatil (Delagrange, France), Dolmatil (Squibb), Equilid (Merrell Dow), Levopraid (Ravizza, Italy), Miradol (Mitsui, Japan), Mirbanil (Boehringer, Germany), Neuromyfar (Emifar, Spain), Sulpril (Astra), Tohpiride (Toyo Pharma, Japan).

Sultopride [*53583-79-2*], *N*-[(1-ethyl-2-pyrro-lidinyl)methyl]-5-(ethylsulfonyl)-2-methoxybenz-amide, $C_{17}H_{26}N_2O_4S$, M_r 354.47, *mp* 181 –182 °C, is related to sulpiride and is prepared analogously [60].

Trade Names. Barnetil (Delagrange, France), Barnotil (Vita, Italy), Topral (Alkaloid, Yugoslavia).

Tiapride [*51012-32-9*], *N*-[2-(diethylamino)-ethyl]-2-methoxy-5-(methylsulfonyl)benzamide, $C_{15}H_{24}N_2O_4S$, M_r 328.43, *mp* 123 – 125 °C, is prepared by activating 2-methoxy-5-(methylsulfonyl)benzoic acid with ethyl chloroformate and reacting the mixed anhydride with 2-(diethylamino)ethylamine [61].

Trade Names. Delpral (Bender, Austria), Equilum (Fumouze, France), Gramalil (Fujisawa, Japan), Luxoben (Chinoin, Italy), Porfanil (Prodes, Spain), Tiaprizal (Delagrange, France).

Amisulpride [*71675-85-9*], 4-amino-*N*-[(1-ethyl-2-pyrrolidinyl)methyl]-5-(ethylsulfonyl)-2-methoxybenzamide, $C_{17}H_{27}N_3O_4S$, M_r 369.48, *mp* 126 – 127 °C, is prepared in an analogous way to tiaprides. 2-Aminomethyl-1-ethylpyrrolidine is condensed with the appropriate benzoic acid derivative in the presence of

ethyl chloroformate [62] or with a benzoyl chloride derivative. In the latter case, the aromatic ring bears a nitro group which is then reduced [63]. Amisulpride is used against both negative and productive symptoms of schizophrenia.

Trade Name. Solian (Delagrange, France).

Remoxipride [*80125-14-0*], (*S*)-3-bromo-2,6-dimethoxy-*N*-(1-ethyl-2-pyrrolidinyl)methyl]-benzamide, $C_{16}H_{23}BrN_2O_3$, M_r 371.23, *mp* 184–185 °C, is prepared by condensing the appropriate benzoyl chloride derivative with the optically active 1-ethyl-2-(aminomethyl)pyrrolidine [64]. Like sulpiride, remoxipride seems to have a specific action on the mesolimbic dopaminergic system and a lower impact on the striatal dopaminergic system, therefore generating less extrapyramidal side effects [65].

Trade Name. Roxiam (Astra, Denmark).

Clebopride [*55905-53-8*], 4-amino-*N*-(1-benzyl-4-piperidyl)-5- chloro-2-methoxybenzamide, $C_{20}H_{24}ClN_3O_2$, M_r 389.88, *mp* 194–195 °C, for preparation see [66].

Trade Names. Clanzol (Orfi, Spain), Clebon (Wyeth), Cleboril (Almirall, Spain), Vuxolin (Carlo Erba).

Metoclopramide [*364-62-5*], 4-amino-5-chloro- *N*-[2-(diethylamino)ethyl]-2-methoxybenzamide, $C_{14}H_{22}ClN_3O_2$, M_r 299.81, *mp* 146–148 °C, is widely used as an antiemetic; for preparation see [67].

Trade Names. Cerucal (Arzneimittelwerk Dresden, Germany), Duraclamid (Durachemie, Germany), Elieten (Nippon Kagaku, Japan), Emex (Beecham), Gastrese LA (Robins, USA), Gastromax (Farmitalia, Italy), Maxeran (Delagrange, France), Maxolon (Beecham), Meclopran (Lagap, Switzerland), Metramid (Nicholas), Moriperan (Morishita, Japan).

Veralipride [*66644-81-3*], *N*-[(1-allyl-2- pyrrolidinyl)methyl]-5-sulfamoyl-5-veratramide, $C_{17}H_{25}N_3O_5S$, M_r 383.5, for preparation see [68]. It is also used to treat menopausal disorders.

Trade Names. Accional (Fides, Spain), Agradil (Vita, Italy), Agréal (Delagrange, France), Faltium (Prodes, Spain), Verapril (Midy, Italy).

2.7. Miscellaneous Neuroleptics

Molindone [*7416-34-4*], 3-ethyl-2-methyl-5-(morpholinomethyl)-4,5,6,7-tetrahydro-1*H*-indol-4-one, $C_{16}H_{24}N_2O_2$, M_r 276.37, *mp* 180–181 °C, is prepared in two steps. Condensation

of cyclohexane-1,2-dione with a keto-oxime affords the indolic ring system. Mannich condensation with morpholine completes the synthesis [69].

Trade Names. Lidone (Abbott), Moban (Endo, USA).

Oxipertine [*153-87-7*], 5,6-dimethoxy-2-methyl-3-[2-(4-phenyl-1-piperazinyl)ethyl]indole, $C_{23}H_{29}N_3O_2$, M_r 379.5, *mp* 250 – 252 °C, is prepared by condensation of an indoleacetic acid derivative with *N*-phenyl-piperazine, followed by reduction [70].

Trade Names. Equipertine (Sterling, Belgium), Forit(Winthrop, Switzerland), Integrin (Sterling, UK), Opertil (Winthrop, Denmark).

2.8. Neuroleptics Under Development

Novel strategies for the treatment of schizophrenia have arisen from the recognition of the possible benefits from additional antagonism at neurotransmitter receptors other than those for dopamine. Thus, several drugs under development act at multiple receptors [71]. *Risperidone* [*106266-06-2*] (R-64 766, Janssen) is a benzisoxazole derivative with mixed D_2/5-HT_2 blocking properties; it is reported to improve negative signs of schizophrenia accompanied with only few motor side effects. *Amperozide* [*75558-90-6*] (FG-5606, Kabi), *ICI 204,636* [*111374-72-2*], and *HP 873* [*133454-47-4*] (Hoechst) are other drugs showing high affinity for 5-HT_2 receptors subjected to clinical investigation for schizophrenia. *Org-5222* [*85650-56-2*] (Organon) is active on a range of receptors including D_1, D_2, α_1, α_2, 5-HT_2, and H_1 receptors; it also antagonizes dopaminomimetics in rodents [72]. Drugs acting at 5-HT_3 receptors have potential interest as antipsychotics [73], e.g., *drolasetron* [*115956-13-3*] (MDL-73147, Marion Merrell Dow) and *zacopride* [*90182-92-6*] (AHR-11190, American Home Products). Most neurotransmitters are subject to a negative-feedback control by presynaptic autoreceptors that prevent further release by activating K^+ channels and/or inhibiting Ca^{2+} channels. Thus the stimulation of presynaptic receptors induces inhibition of transmitter release. Dopaminergic activity can be reduced not only by postsynaptic receptor antagonism, but also by activation of presynaptic autoreceptors. *Roxindole* [*112192-04-8*] (EMD-49980, E. Merck) and *CGS-15873* [*118929-49-0*] (Ciba-Geigy) [74] mimick this feedback inhibition mechanism for endogenous dopamine; they have an antipsychotic-like pharmacological profile. Other antipsychotics under development include antiaggression drugs such as *eltoprazine* [*98224-03-4*] (DU-28853, Solvay), and the glycine prodrug *milacemide* [*76990-56-2*] (CP-15525, Monsanto), which also has antidepressant and cognitive-enhancing potential. Other compounds act as specific D_2- or D_1-receptor antagonists (for a review, see [75]).

3. Antidepressants

Depression corresponds to major modifications of mood and is characterized by affective disorders that extend outside acceptable limits and impair thinking and perception. Most depressive patients suffer only from unipolar or major depression. In others, depression is associated with intermittent episodes of mania (manic-depressive illness). Major depression is characterized by sadness, despair, self-depreciation, insomnia, anorexia, and also sometimes suicidal behavior. Manic-depressive illness is characterized by dysphoria, irritability, marked insomnia,

impaired judgement, or behavior. Major depression and manic-depressive illness appear to react to different treatments.

Treatment of depression was first based on the sedative effect of opium (laudanum) or on the psychostimulant activity of amphetamines. At the end of the 1950s, KUHN discovered that imipramine, a dibenzazepine derivative first tested for its antipsychotic and antihistaminic properties, was a powerful antidepressive agent in clinical trials [76]. Simultaneously, KLINE successfully used iproniazide, an isoniazide derivative used as a drug against tuberculosis, in the treatment of depression [77]. The discovery of imipramine stimulated the search for related compounds based on the tricyclic dibenzazepine structure. Iproniazide was found to be an irreversible inhibitor of monoamine oxidase, a result which also stimulated further research.

3.1. Tricyclic Antidepressants

Tricyclic antidepressants have been widely used as the drugs of choice for the treatment of major depression. In behavioral studies in rodents, tricyclics depress spontaneous motor activity and impair the acquisition and performance of a conditioned avoidance test. Their best recognized psychopharmacological characteristic corresponds to their interaction with reserpine and tetrabenazine which deplete biogenic amines in the brain. The tests used most frequently to predict the antidepressant effect of a drug are based on the inhibition of sedation, catalepsy, hypothermia, or ptosis in rodents pretreated with reserpine [78]. In electroencephalographic (EEG) studies, low doses induce synchronization which reflects sedative activity; high doses produce a desynchronized EEG and are sometimes able to induce EEG epileptogenic events [79, 80]. Moreover, in sleep–wakefulness studies, these drugs often increase slow-wave sleep and decrease paradoxical sleep.

Under normal conditions neurotransmitters in the synapse are taken up by the cell. Uptake inhibitors bind to specific sites and impede physiological uptake; neurotransmitters (NA, DA, or 5-HT) thus show higher concentrations for longer in the synaptic cleft and induce more intense neuronal activity. In contrast an enhancer of 5-HT uptake increases the physiological uptake of the transmitter and thus decreases its synaptic concentration.

Tricyclic antidepressants potentiate the action of biogenic amines [mainly noradrenaline (NA) and serotonin (5-hydroxytryptamine, 5-HT)] by inhibiting their presynaptic uptake after release which leads to increased concentrations of these neurotransmitters at the synapse. None of the compounds in this series are purely selective inhibitors for NA or 5-HT uptake [81, 82]. For example, desipramine is most active in blocking NA uptake and has a low efficacy on 5-HT uptake, while amitriptyline is equipotent in blocking both NA and 5-HT uptake.

3.1.1. Inhibitors of Noradrenaline and/or Serotonin Uptake

Amitriptyline [*50-48-6*], 10,11-dihydro-5-(3-dimethylaminopropylidene)-5*H*-dibenzo[*a,d*]cycloheptene, $C_{20}H_{23}N$, M_r 277.39, hydrochloride *mp* 196 – 197 °C; this compound can be prepared by reaction of 5-oxo-10,11-dihydro-5*H*-dibenzo[*a,d*]cycloheptene with the Grignard reagent of 3-dimethylaminopropyl chloride followed by dehydration of the resulting tertiary alcohol in a strongly acidic medium [83–85]. Amitriptyline and other tricyclic antidepressants are particularly effective in the treatment of endogeneous depressions, but are less effective in reactive depression.

Trade Names. (Hydrochloride) Adepril (Merrell Dow Lepetit), Amitid (Squibb), Amitril (Warner-Chilcott), Endep, Laroxyl (Roche), Lentizol (Warner – Lambert, Parke Davis), Saroten (Lundbeck, Denmark, Tropon, Germany), Sylvemid (Weiner, Germany), Elavil, Tryptanol, Tryptizol (Merck Sharp & Dohme).

Amoxapine [*14028-44-5*], 2-chloro-11-(1-piperazinyc)dibenz[*b,f*][1, 4]oxazepine, $C_{17}H_{16}$-ClN_3O, M_r 313.79, *mp* 175 – 176 °C. Treatment of the starting lactam with phosphorus oxychloride, followed by condensation of the corresponding imidochloride with piperazine affords amoxapine [57].

Amoxapine is a tricyclic antidepressant with actions and uses similar to those of amitriptyline [86].

Trade Names. Asendin, Asendis, Defenyl, Demolox, Moxadil, Omnipress (Lederle).

Clomipramine [*303-49-1*], 3-chloro-10,11-dihydro-5-(3-dimethylaminopropyl)-5*H*-dibenz-[*b,f*]azepine, $C_{19}H_{23}ClN_2$, M_r 314.87, *bp* (0.04 kPa) 160 – 170 °C, hydrochloride *mp* 189 –190 °C. The synthesis of clomipramine is as follows [87]:

Clomipramine is particulary effective in patients with obsessive – compulsive disorders.

Trade Names. (Hydrochloride) Anafranil (Geigy), Hydiphen (Arzneimittelwerk Dresden, Germany), Maronil (Unipharm, Israel).

Dosulepin [*113-53-1*], Dothiepin, 6,11-dihydro-11-(3-dimethylaminopropylidene)dibenzo-[*b,e*]thiepin, $C_{19}H_{21}NS$, M_r 295.45, *bp* (0.006 kPa) 171 – 172 °C, *mp* 55 – 57 °C, hydrochloride *mp* 218 – 221 °C. The synthesis of dosulepin follows [88]:

Trade Names. (Hydrochloride) Idom (Kanoldt, Germany), Prothiaden (Boots; Boots Dacour, France; Spofa, Czechoslovakia), Xerenal (Kwizda, Austria).

Doxepin [*1668-19-5*], 6,11-dihydro-11-(3-dimethylaminopropylidene)dibenz[*b,e*]oxepin, $C_{19}H_{21}NO$, M_r 279.37, *bp* (0.026 kPa) 260 – 270 °C, hydrochloride *mp* 188 – 189 °C. This dibenz[*b,e*]oxepin can be considered as an analogue of amitriptyline (replacement of methylene group by an oxygen atom). The synthesis of doxepin is summarized at next side [89].

Trade Names. (Hydrochloride) Adapin (Pennwalt, USA), Aponal (Galenus, Germany), Novoxapin (Ester, Spain), Quitaxon (Boehringer Mannheim, Erco Denmark), Sinequan (Pfizer-Roerig).

Imipramine [*50-49-7*], 10,11-dihydro-5-(3-dimethylaminopropyl)-5*H*-dibenz[*b,f*]azepine, $C_{19}H_{24}N_2$, M_r 280.40, *bp* (0.013 kPa) 160 °C, hydrochloride *mp* 174 – 75 °C. Imipramine is prepared by alkylation of 10,11-dihydro-5*H*-dibenz[*b,f*]azepine, which is the tricyclic parent structure for a range of psychopharmaceuticals, with 3-dimethylaminopropyl chloride in the presence of sodamide [90]:

The starting material can be obtained by oxidative dimerization of 2-nitrotoluene to give 1,2-bis-(2-nitrophenyl)ethane which is hydrogenated to give the corresponding diamine. Ring closure takes place on heating with elimination of ammonia to afford the parent dibenzazepine.

Imipramine is a tricyclic antidepressant with a similar mode of action and similar uses as amitriptyline but with less marked sedative properties.

Trade Names. (Hydrochloride) Chrytemin (Fujinaga, Japan), Deprinol (Dumex, Denmark), Efuranol (Pfizer), Feinalmin (Sanko, Japan), Imavate (Robins, USA), Janimine (Abbott), Melipramin (Egis, Hungary), Presamine (USV, USA).

Desipramine [*50-47-5*], 10,11-dihydro-5-[3-(methylaminopropyl)-5*H*-dibenz[*b,f*]azepine, $C_{18}H_{22}N_2$, M_r 266.37, *bp* (0.002 kPa) 172 – 174 °C, hydrochloride *mp* 214 – 218 °C. Treatment of imipramine with ethyl chloroformate followed by alkaline hydrolysis affords desipramine in high yield [91].

Trade Names. (Hydrochloride) Norpolake (Lakeside, USA), Norpramin (Merrell Dow Pharmaceuticals), Nortimil (Chiesi, Italy), Pertofran, Sertofren (Geigy).

Lofepramine [*23047-25-8*], *N*-methyl-*N*-(4- chlorobenzoylmethyl)-3-(10,11-dihydro-5*H*-di-benzo[*b,f*]azepin-5-yl)propylamine, $C_{26}H_{27}ClN_2O$, M_r 418.97, *mp* 104 – 106 °C, hydrochloride *mp* 152 – 154 °C. Lofepramine is obtained by reaction of desipramine with 4′-chloro-bromoacetophenone [91].

Trade Names. (Hydrochloride) Deftan, Deprimil, Emdalen, Gamanil, Gamonil (E. Merck, Germany), Tymelyt (Leo, Sweden).

Metapramine [*21730-16-5*], 10,11-dihydro-5-methyl-10-(methylamino)-5*H*-dibenz[*b,f*]azepine, $C_{16}H_{18}N_2$, M_r 238.33, hydrochloride *mp* 238 –240 °C. This compound can be prepared in two ways [92]:

Trade Name. Timaxel (Specia, France).

Nortriptyline [*72-69-5*], 10,11-dihydro-5-(3-methylaminopropylidene)-5*H*-dibenzo[*a,d*]cycloheptene, $C_{19}H_{21}N$, M_r 263.37, hydrochloride *mp* 213 – 215 °C. This compound is prepared as follows [93].

Trade Names. (Hydrochloride) Acetexa (Lilly), Allegron (Dista), Altilev (Squibb), Nortrilen (Lundbeck, Denmark, Tropon, Germany), Pamelor (Lilly, Sandoz-Wander), Sensival (Pharmacia, Sweden), Vividyl (Lilly).

Protriptyline [*438-60-8*], 5-(3-methylaminopropyl)-5*H*-dibenzo[*a,d*]cycloheptene, $C_{19}H_{21}N$, M_r 263.37, hydrochloride *mp* 169 – 171 °C. Protriptyline can be prepared as follows [94]:

Protriptyline has considerably less marked sedative properties than amitriptyline, and may have stimulant effects.

Trade Names. (Hydrochloride) Concordin, Vivactil (Merck Sharp & Dohme), Maximed (Frosst, Germany, Merck Sharp & Dohme), Triptil (Merck-Frosst, Pointe Claire Dorval, Canada, Merck Sharp & Dohme).

Butriptyline [*35941-65-2*], 10,11-dihydro-5-(3-dimethylamino-2-methylpropyl)-5*H*-dibenzo-[*a,d*]cycloheptene, $C_{21}H_{27}N$, M_r 293.46, *bp* (0.133 kPa) 180 – 185 °C, hydrochloride *mp* 188 – 190 °C. The intermediate olefinic compound is prepared analogously to the amitriptyline parent olefin (see page 18), and finally reduced with $LiAlH_4$ [95].

Trade Names. Centrelyse, Evadene (Ayerst), Evadyne (Ayerst), Evasidol (Arcana, Austria).

Quinupramine [*31721-17-2*],10,11-dihydro-5-(3-quinuclidinyl)-5*H*-dibenz[*b,f*]azepine, $C_{21}H_{24}N_2$, M_r 304.43, hydrochloride *mp* 150 °C, is prepared as follows [96]:

Trade Names. Kevopril (Rhône-Poulenc), Kinupril (Pharmuka, France), Quinuprine (Rhone, Spain).

3.1.2. Enhancers of Uptake

Tianeptine [*66981-73-5*], 7-[(3-chloro-6,11-dihydro-6-methyldibenzo[*c,f*][1, 2]thiazepin-11-yl)amino]heptanoic acid *S,S*-dioxide, $C_{21}H_{25}ClN_2O_4S$, M_r 436.95, sodium salt *mp* 180 °C. Tianeptine is prepared as follows [97]:

Tianeptine is used in the treatment of reactive and neurotic depression, as well as in the treatment of anxious states.

Trade Name. Stablon (Ardix, France).

3.1.3. Inhibitors of Dopamine Uptake

Amineptine [*57574-09-1*], 7-[(10,11-dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-yl)amino]heptanoic acid, $C_{22}H_{27}NO_2$, M_r 337.47, hydrochloride *mp* 226 – 230 °C, is prepared as follows [98]:

Trade Names. Directim, Neolior, Viaspera (Servier, France), Maneon (Poli, Italy), Provector (Servier, Euthé-rapie, France).

3.1.4. Other Tricyclic Antidepressants

Carpipramine [*5942-95-0*], 5-{3-[4-carbamoyl-4-piperidino)piperidino]propyl}-10,11-dihydro-5*H*-dibenz[*b,f*]azepine, also has neuroleptic properties (see Section 2.5.1).

Demexiptiline [*24701-51-7*], 5*H*-dibenzo[*a,d*]cyclohepten-5-one, *O*-[2-(methylamino)-ethyl]oxime, $C_{18}H_{18}N_2O$, M_r 278.35, hydrochloride *mp* 232 – 233 °C. Demexiptiline is prepared as follows [99]:

Trade Name. Déparon (Aron, France).

Dibenzepin [*4498-32-2*], 10,11-dihydro-10-(2-dimethylaminoethyl)-5-methyl-11-oxodibenzo[*b,e*][1, 4]diazepine, $C_{18}H_{21}N_3O$, M_r 295.37 *mp* 116 – 117 °C, hydrochloride *mp* 238 °C. Dibenzepin is prepared as follows [100]:

Trade Names. Ecatril, Neodit (Sandoz-Wander).

Noxiptilin [*3362-45-6*], 10,11-dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-one, *O*-[2-(dimethylamino)ethyl]oxime, $C_{19}H_{22}N_2O$, M_r 294.4, *bp* (0.006 kPa) 160 – 164 °C, hydrochloride *mp* 185 –187 °C. Noxiptilin is prepared as follows [101]:

Trade Names. Agedal (Bayer), Nogedal (Théraplix, France), Sipcar (Bernabo, Argentina).

Opipramol [*315-72-0*], 4-[3-(5*H*-dibenz[*b,f*]- azepin-5-yl)propyl]-1-(2-hydroxyethyl)piperazine, $C_{23}H_{29}N_3O$, M_r 363.49, *mp* 100 – 101 °C, dihydrochloride *mp* 228 – 230 °C. Opipramol is prepared as follows [102]:

Trade Names. Deprenil (Yurtoglu, Turkey), Dinsidon, Ensidon, Insidon, Nisidana (Geigy).

Propizepine [*10321-12-7*], 6,11-dihydro-6-[2-(dimethylamino)propyl-5*H*-pyrido[2,3-*b*][1,5]-benzodiazepin-5-one, $C_{17}H_{20}N_4O$, M_r 296.38, *mp* 122 °C, hydrochloride, *mp* 235 °C [103]

Trade Names. Depressin, Vagran (UPSA, France).

Trimipramine [*739-71-9*], 10,11-dihydro-5-[3-(dimethylamino)-2-methylpropyl]-5*H*-dibenz[*b,f*]azepine, $C_{20}H_{26}N_2$, M_r 294.42, *mp* 45 °C, maleate salt *mp* 142 °C. The shortest synthesis of trimipramine is shown below [104]:

Trade Names. Surmontil (Specia, May & Baker, Farmitalia Carlo Erba), Stangyl (Rhône-Poulenc).

3.2. Tetracyclic Antidepressants

Maprotiline and mianserin constitute a second generation of antidepressants that are chemically characterized by a tetracyclic structure. In animal models, *maprotiline*, a dibenzobicyclooctadiene derivative, has a sedative and tranquilizing activity [105]. Clinical studies have demonstrated its activity to be equivalent to that of the tricyclic antidepressants [106], but with less cardiac side effects. Maprotiline has a potent activity in blocking NA uptake without effect on 5-HT uptake [105].

Mianserin is a tetracyclic piperazinoazepine first developed as an antihistamine and anti-5-HT drug. It has antidepressant activity in humans and induces drowsiness during the first weeks of treatment; its possible cardiotoxic effects are less marked than those observed with tricyclic antidepressants [107]. Mianserin is a potent inhibitor of H_2-receptor-mediated adenylate cyclase formation in brain [108] and has a presynaptic α-adrenoreceptor blocking effect [109]. Its mechanism of action appears to involve release of NA via cortical α_2-adrenergic autoreceptor blockade.

Maprotiline [*10262-69-8*], 1-(3-methylaminopropyl)dibenzo[*b,e*]bicyclo[2.2.2]octadiene, $C_{20}H_{23}N$, M_r 277.41, *mp* 92 – 94 °C, hydrochloride *mp* 230 – 232 °C. Maprotiline is prepared as follows [110]:

Maprotiline differs structurally from tricyclics due to the presence of an additional alicyclic bridge. It resembles amitriptyline with regard to both efficacy and side effects. It may have proconvulsant properties.

Trade Name. Ludiomil (Ciba).

Mianserin [*24219-97-4*], 2-methyl-1,2,3,4,10, 14*b*-hexahydro-2*H*-pyrazino[1,2-*f*]morphanthridine, $C_{18}H_{20}N_2$, M_r 264.37, hydrochloride *mp* 282 – 284 °C. Mianserin is prepared as follows [111]:

Mianserin does not display significant antimuscarinic properties, but has a marked sedative action.

Trade Names. Athymil, Bolvidon, Lantanon, Tetramide, Tolvin, Tolvon (Organon).

3.3. Monoamine Oxidase Inhibitors (MAOI)

Low single doses of MAOI produce only minor or negligible changes in animal behavioral pharmacology even when a significant increase in biogenic amines is measured in the brain. Nevertheless, combined with other agents such as reserpine or tetrabenazine (which induce biogenic amine depletion), they tend to produce excitement rather than sedation in rodents. MAOI have only slight effects on EEG recordings, with the exception of tranylcypromine which is a psychostimulant. They are amongst the most effective drugs in suppressing paradoxical (rapid eye movement, REM) sleep in humans and are used in narcolepsy for this reason.

Monoamine oxidase (MAO) is a complex enzyme which is responsible for the metabolic degradation of biogenic amines. Drugs which inhibit this enzyme system therefore induce an increase in the concentration of biogenic amines such as adrenaline, NA and 5-HT which explains their antidepressant effect [112]. MAO occurs in two forms that differ in their preferences for substrates and sensitivities to selective inhibitors: MAO-A preferentially acts on NA and 5-HT in humans and MAO-B acts on phenethylamine, methylhistamine, and dopamine (DA). Irreversible MAOIs bind covalently to the enzyme, involving noncompetitive inhibition. Recovery of MAO activity is only achieved by arrival of newly synthesized enzyme. Reversible MAOIs form a less stable bond with the enzyme and they can be removed from their binding site, MAO activity therefore recovers.

3.3.1. Hydrazine Derivatives

Benmoxine [*7654-03-7*], benzoic acid 2-(1-phenylethyl)hyrazide, $C_{15}H_{16}N_2O$, M_r 240.29, *mp* 93 – 94 °C. Hydrogenation of the hydrazone obtained by condensation of acetophenone with benzoylhydrazine affords benmoxine [113].

Trade Names. Nerusil (Iquinosa, Spain); Neuralex (Millot, France).

Iproclozide [*3544-35-2*], (4-chlorophenoxy)-acetic acid 2-isopropylhydrazide, $C_{11}H_{15}ClN_2O_2$, M_r 242.72, *mp* 93 – 94 °C. Iproclozide is prepared as follows [114]:

Trade Name. Sursum (Merrell Dow Pharmaceuticals, Ibsa, Switzerland).

Iproniazid [*54-92-2*], isonicotinic2-isopropylhydrazide, $C_9H_{13}N_3O$, M_r 179.22, *mp* 112.5 –113.5 °C, can be prepared using the synthetic pathway described for iproclozide [115]. An alternative synthesis is described in [116].

Trade Names. Ipronid (Afi, Norway), Marsilid (Roche).

Isocarboxazid [*59-63-2*], 5-methyl-3-isoxazolecarboxylic acid 2-benzylhydrazide, $C_{12}H_{13}N_3O_2$, M_r 231.25, *mp* 105 – 106 °C. Isocarboxazid is prepared according to the following scheme [117]:

Trade Names. Marplan, Marplon (Roche).

Nialamide [*51-12-7*], isonicotinic acid 2-(2-benzylcarbamoylethyl)hydrazide, $C_{16}H_{18}N_4O_2$, M_r 298.34, *mp* 152 – 153 °C [118].

Trade Names. Espril (Saba, Turkey), Niamide (Pfizer-Roerig), Nuredal (Egis, Hungary), Surgex (Firma, Italy).

Phenelzine [*51-71-8*], phenethylhydrazine, $C_8H_{12}N_2$, M_r 136.19, *bp* (0.013 kPa) 74 °C, hydrochloride *mp* 174 °C, for preparation see [119].

Trade Names. (Acid sulfate) Nardelzine (Substancia, the Netherlands, Substancia-Parke Davis, Spain, Warner-Chilcott), Nardil (Warner-Chilcott, Parke-Davis).

3.3.2. Nonhydrazine Derivatives

Caroxazone [*18464-39-6*], 2-oxo-1,3-benzoxazine-3(4H)-acetamide, $C_{10}H_{10}N_2O_3$, M_r 206.20, *mp* 203 – 205 °C. Caroxazone is prepared as follows [120]:

Trade Name. Timostenil(Farmitalia Carlo Erba, Italy).

Milacemide [*76990-56-2*], 2-pentylaminoacetamide, $C_7H_{16}N_2O$, M_r 144.14, *mp* 46 °C, is prepared by condensation of pentylamine with chloroacetamide [121].

Trade Names. Glyzac, Glyzan (Searle).

Pargyline [*555-57-7*], *N*-methyl-*N*-2-propynylbenzylamine, $C_{11}H_{13}N$, M_r 159.22, hydrochloride *mp* 154 – 155 °C, is prepared by condensation of propynyl bromide with benzylmethylamine [122].

Pargyline is also an antihypertensive agent.

Trade Names. Eudatine, Eutonyl (Abbott).

Selegiline [*14611-51-9*], (*R*)-*N*,α-dimethyl-*N*-2-propynylphenethylamine, $C_{13}H_{17}N$, M_r 187.14, *bp* (0.08 kPa) 92 – 93 °C, hydrochloride *mp* 141.0 – 141.5 °C. Selegiline can be prepared according to various schemes, the shortest is shown below [123]:

Selegiline is used in the treatment of Parkinson's disease.

Trade Names. Eldeprine (Unicet, France), Jumex (Chinoin, Hungary, Chiesi, Italy), Jumexal (Labatec, Switzerland), Movergan (Asta-Degussa, Germany, Astra).

Tranylcypromine [*155-09-9*], *trans*-(±)-2-phenylcyclopropylamine, $C_9H_{11}N$, M_r 133.19, *bp* (0.20 – 0.213 kPa) 79 – 80 °C, hydrochloride *mp* 164 – 166 °C; for preparation, see [124].

Tranylcypromine is used for the treatment of adult outpatients with reactive depression.

Trade Names. (Sulfate salt) Parnate (Smith Kline & French, Röhm Pharma, Germany), Transapin (Medexport, Independent Estates Community), Tylciprine (Théraplix, France).

3.3.3. Reversible MAO-A Inhibitors

Metralindole [*54188-38-4*], 3-methyl-8-methoxy-3*H*-1,2,5,6-tetrahydropyrazino[1,2,3-*ab*]-*β*-carboline, $C_{15}H_{17}N_3O$, M_r 255.14, *mp* 164 –166 °C. Metralindole is prepared as follows [125]:

Trade Name. (Sulfate salt) Incazan (Independent Estates Community).

Moclobemide [*71320-77-9*], 4-chloro-*N*-(2-morpholinoethyl)benzamide, $C_{13}H_{17}ClN_2O_2$, M_r 268.7, *mp* 137 °C. Various syntheses are described for moclobemide, the simplest and shortest being the reaction of 4-chlorobenzoyl chloride with *N*-(2-aminoethyl)morpholine in pyridine [126].

Trade Name. Auroxix (Roche, Switzerland).

Pirlindole [*60762-57-4*], 8-methyl-1,2,3,4-tetrahydro-1,10-trimethylenepyrazino[1,2-a]indole, $C_{15}H_{18}N_2$, M_r 226.14, hydrochloride, *mp* 260 –261 °C. It can be prepared in two ways (Fig. 2) [127].

Trade Names. Lifril (Casen Fisons, Spain), Pyrazidol (Independent Estates Community).

Toloxatone [*29218-27-7*], 5-(hydroxy-methyl)-3-m-tolyl-2-oxazolidinone, $C_{11}H_{13}NO_3$, M_r 207.2, *mp* 76 °C is prepared by the reaction of 3-methylaniline with glycidol followed by condensation of the intermediate (an aminoalcohol) with diethyl carbonate [128].

Trade Name. Humoryl (Delalande, France).

3.4. Inhibitors of Serotonin Uptake

During the 1980s new drugs were developed that differed from tricyclics because they were highly selective serotonin (5-HT) uptake inhibitors, (e.g., fluvoxamine, paroxetine, fluoxetine, or sertraline). They proved to be effective antidepressants in humans [129].

Fluoxetine enhances behavioral patterns induced in rodents by pharmacological facilitation of 5-HT transmission [130]. It potentiates 5-HT-induced head twitches in mice pretreated with

Figure 2. Synthesis of pirlindole

pargyline, and has also been used as a tool in assessing 5-HT transmission in several behavioral paradigms (self-stimulation test). Nevertheless, in the behavioral despair test, where rats are immobile after a short period of swimming in a restricted place, fluoxetine does not significantly reduce the duration of immobility as is the case following administration of antidepressants that inhibit biogenic amine uptake [106, 131]. Fluoxetine and related compounds are specific 5-HT uptake inhibitors. They have no affinity for receptors such as cholinergic (muscarinic), α-adrenergic, or histaminergic, and they possess lower, cardiovascular and sedative side effects than the tricyclic antidepressants. Trazodone is an inhibitor of synaptosomal 5-HT uptake but is also a 5-HT antagonist (see Section 3.6) [132].

The compounds described below are specific inhibitors of 5-HT uptake. An exception is oxaflozane, which also inhibits NA uptake.

Citalopram [*59729-33-8*], 1,3-dihydro-1-[3-(dimethylamino)propyl]-1-(4-fluorophenyl)-5-iso-benzofurancarbonitrile, $C_{20}H_{21}FN_2O$, M_r 324.40, *bp* (0.004 kPa) 175 – 181 °C, hydrobromide *mp* 182 – 183 °C. Citalopram is prepared as follows [133]:

Citalopram is also used as a geriatric drug [134].

Trade Names. Cipramil (Lundbeck, U.K.), Seropam (Zeria).

Femoxetine [*59859-58-4*], (3*R-trans*)-3-[4-(methoxy)phenoxymethyl]-1-methyl-4-phenylpiperidine, $C_{20}H_{25}NO_2$, M_r 311.43. This compound is prepared as follows [135]:

This 5-HT uptake inhibitor is as effective as amitriptyline in the treatment of depression, but displays fewer side effects.

Trade Name. Malexil (Ferrosan, Bristol-Myers, Knoll).

Fluoxetine [*54910-89-3*], *N*-methyl-3-[4-trifluoromethylphenoxy-3-phenylpropylamine, $C_{17}H_{18}F_3NO$, M_r 309.33, oxalate *mp* 179–182 °C (decomp.). Fluoxetine is prepared as follows [136]:

This 5-HT uptake inhibitor is reported to display fewer antimuscarinic side effects than tricyclic antidepressants.

Trade Names. Adofen (Ferrer, Spain), Fluoxeren (Menerini, Italy), Fontex (Lilly), Reneuron (Juste, Spain), Prozac (Lilly).

Fluvoxamine [*54739-18-3*], 5-methoxy-4′-(tri-fluoromethyl)valerophenone(E)-O-(2-aminoethyl)-oxime, $C_{15}H_{21}F_3N_2O_2$, M_r 318.35, maleate *mp* 120–121.5 °C. Fluvoxamine is prepared as follows [137]:

The compound has a good selectivity for 5-HT uptake over noradrenaline uptake.

Trade Names. Avoxin (Krka, Yugoslavia), Dumirox (Kalifarma, Spain), Faverin, Fevarin, Floxyfral, Floxytral, Myroxim (Duphar).

Oxaflozane [*26629-87-8*], 4-isopropyl-2-[3-(tri-fluoromethyl)-phenyl]morpholine, $C_{14}H_{18}F_3NO$, M_r 273.29, *bp* (0.0006 kPa) 52 °C, hydrochloride *mp* 164 °C. Oxaflozane is prepared as follows [138]:

Trade Name. Conflictan (LTM Sarbach, France).

Paroxetine [*61869-08-7*], (−)-*trans*-4-(4-fluorophenyl)-3-{[3,4-(methylenedioxy)phenoxy]-methyl}-piperidine, $C_{19}H_{20}FNO_3$, M_r 329.37, hydrochloride *mp* 118 °C. This piperidine derivative is prepared by condensation of 4-(4-fluorophenyl)-3-(hydroxymethyl)piperidine with 3,4-methylenedioxyphenol in the presence of dicyclohexylcarbodiimide [139].

Trade Names. Aropax (Beecham Laboratories, USA), Seroxat (Ferrosan).

Sertraline [*79617-96-2*], (1*S*,4*S*)-4-(3,4-dichlorophenyl)-1,2,3,4-tetrahydro-*N*-methyl-1-naphthylamine, $C_{17}H_{17}Cl_2N$, M_r 306.23, hydrochloride, *mp* 243 – 245 °C. For the synthesis of sertraline, see [140].

Trade Name. Lustral (Invicta and Pfizer, UK).

3.5. Lithium

Despite the discovery in 1949 of the value of lithium salts, their use as a therapy for mania only became current at the end of the 1950s in Europe, and only in the early 1970s in the United States. Lithium salts have proven to be active in mania and to reduce the frequency of attacks of manic depressive illness [141, 142]. In experimental psychopharmacology lithium salts only show weak activity. A sedative effect may be seen at high doses, but is less evident than with antipsychotics. Lithium salts do not antagonize stereotypies induced by amphetamine or apomorphine (tests for neuroleptic activity) nor the effects of reserpine or tetrabenazine (tests for antidepressant activity). In manic patients, lithium salts improve slow-wave sleep but depress REM sleep; lithium induces slow-wave activity, sometimes with superimposed fast frequencies [79].

The mechanism of action of lithium salts is poorly understood. Lithium acts on biological membranes and reduces excitability at therapeutic concentrations (1 m Eq/L). Lithium has similar ionic properties to sodium but is not the ideal substrate for the transmembrane sodium pump and thus cannot maintain membrane potentials. This leads to a decrease in excitability, which could correspond to the reduction of the psychic reactivity of the patient. Nevertheless biochemical studies have demonstrated that lithium (1 – 10 m Eq/L) inhibits release of NA and DA but not that of 5-HT [143].

Second messengers, such as inositol phosphates, are released by hydrolysis of membrane phosphatidylinositides after activation of the neurotransmitter receptors; lithium can increase this release. Depletion of phosphatidyinositides reduces neuron reactivity to muscarinic, α, – adrenergic, or other stimuli where phosphatidylinositol is the second messenger. This suggests that lithium could preferentially act on hyperactive cells which induce the manic depressive illness [144] and the noradrenergic system which abnormally increases brain electrical activity.

Finally, studies have shown that lithium can interact with other antidepressants and enhance their efficacy by acting on 5-HT neurotransmission. Studies in rats and cats have shown that tryptophan concentration and uptake are increased after short- or long-term lithium treatment. Short-term treatment with lithium has no effect on basal 5-HT release in the hippocampus or frontal cortex. Studies with lithium salts on 5-HT function indicate that they act at various levels, including reuptake, release, synthesis, storage, or receptor interactions; many of these effects are time, region, or species dependent.

Trade Names. (Carbonate) Teralithe (Rhône-Poulenc Rorer, France), (gluconate) Neurolithium (Labcatal, France).

3.6. Miscellaneous Antidepressants

Amfebutamone [*34911-55-2*], 2-(*tert*-butylamino)-3′-chloropropiophenone, $C_{13}H_{18}ClNO$, M_r 293.74, *bp* (0.0006 kPa) 52 °C, hydrochloride *mp* 233 – 234 °C. Amfebutamone can be prepared as follows [145]:

Amfebutamone is an inhibitor of dopamine uptake.

Trade Names. Wellbatrin, Wellbutrin (Burroughs Wellcome).

Medifoxamine [*32359-34-5*], *N,N*-dimethyl-2,2-diphenoxyethylamine, $C_{16}H_{19}NO_2$, M_r 257.33, fumarate *mp* 128.5 °C. Medifoxamine is prepared as follows [146]:

The mechanism of action of medifoxamine is analogous to that of amfebutamone.

Trade Names. Clédial (Anphar-Rolland, France), Gerdaxyl (Gerda, France; Promesa, Spain).

Trazodone [*19794-93-5*], 2-{3-[4-(3-chlorophenyl)-1-piperazinyl]propyl}-1,2,4-triazolo[4,3-*a*]pyridin-3(2*H*)-one, $C_{19}H_{22}ClN_5O$, M_r 371.88, *mp* 86 – 87 °C, hydrochloride *mp* 223 °C. The bicyclic starting material is prepared by condensation of 2-chloropyridine with semicarbazide [147]:

The triazolopyridine derivative trazodone is special because it is not active in classical animal models, such as reserpine antagonism [148], but potentiates the behavioral changes induced by the 5-HT precursor 5-hydroxytryptophan. Nevertheless its efficacy as an antidepressant drug has been proved in clinical trials, with fewer side effects (e.g., cardiotoxicity) and a larger safety margin than the tricyclics. Drowsiness is, however, common [106]. Trazodone is a selective inhibitor of central 5-HT uptake and decreases peripheral 5-HT uptake. It also increases the turnover of brain dopamine.

Trade Names. Beneficat (Nemi, Argentina), Depyrel (Abic, Israel), Desyrel (Angelini, Italy, Bristol-Meyers, Mead-Johnson), Molipaxin (Roussel), Pragmazone (UPSA, France), Taxagon (Rhodia, Argentina), Tombran (Boehringer, Ingelheim), Trazodil (Unipharm, Israel).

Viloxazine [*46817-91-8*], 2-[(2-ethoxyphenoxy)methyl]tetrahydro-1,4-oxazine, $C_{13}H_{19}NO_3$, M_r 237.3, hydrochloride, *mp* 185 – 186 °C. For preparation, see [149].

This derivative is devoid of cholinergic-type side effects and is as potent as the standard tricyclic antidepressants. Viloxazine is particularly useful for treating depression in the elderly.

Trade Names. Catarol, Vivalan, Vivarint (ICI).

3.7. Antidepressants Under Development

Adinazolam [*37115-32-5*] is a triazolobenzodiazepine under development (Upjohn) as an antidepressant and anxiolytic (preregistration). It has a rapid onset of action with minimal anticholinergic side effects [150]. *Brofaromine* [*63638-91-5*], (a benzofuranylpiperidine derivative, (Ciba-Geigy), is a selective, competitive, reversible MAO-A inhibitor (phase III clinical trials). Side effects were less frequent than with imipramine or tranylcypromine [151]. *Cericlamine* [*112922-55-1*] (Jouveinal), a potent and selective monocyclic 5-HT uptake inhibitor, is claimed to exhibit a better safety profile than other new-generation antidepressants. Chemically related to buspirone, *gepirone* [*83928-76-1*] is a partial 5-HT-1 A agonist under development by Bristol-Myers Squibb [152]. *Milnacipran* [*92623-85-3*] is a cyclopropanecarboxamide derivative which behaves as a 5-HT and NA uptake inhibitor (preregistration, Pierre Fabre). Wyeth-Ayerst (American Home Products) has developed *venlafaxine* [*99300-78-4*], which has a binding profile identical with that of milnacipran (phase III clinical trials). *Mirtazapine* [*85650-52-8*] (Organon), an analog of mianserin, blocks presynaptic α-receptors (preregistration). EEG studies on humans have confirmed its antidepressant potential [153]. The nontricyclic triazolone derivative *nefazodone* [*83366-66-9*] is an antidepressant under development by Bristol-Myers Squibb (preregistration). Farmitalia Carlo Erba (Erbamont) is developing *reboxetine* [*71620-89-8*], which inhibits NA reuptake and blocks α_2-receptors (phase III clinical trials). *Ritanserin* [*87051-43-2*], a thiazolopyrimidine is a selective 5-HT_2 antagonist. The compound is under development by Janssen (phase III clinical trials) and is effective in mild to moderate depression, possibly associated with anxiety. Inhibitors of brain type II phosphodiesterase, such as *rolipram* [*61413-54-5*] (Schering AG), also have antidepressant activity. They possibly act by enhancing the second messenger concentrations involved in β-adrenoreceptor activation [154]. Rolipram was as effective as amitriptyline in treating patients with manic-depressive psychosis [155].

Efforts are continuing to elucidate the mechanism of action of antidepressants, and to develop new behavioral models with better predictability. Potentially interesting are compounds with combined properties (e.g., MAO inhibitor with uptake blocking activity).

4. Anxiolytics

Anxiety can be considered as a normal psychophysiological function which, in certain situations, may present a pathological feature due to its intensity and the excessive responses that it produces. Anxiety may be acute or chronic, and may take many forms such as generalized anxiety, phobias, anguish, or panic attacks. The aim of the anxiolytics is to treat the psychological and physiological effects of anxiety.

Alcohol and opium were probably the first substances used in the ancient times for their anxiolytic and hypnosedative properties, despite their undesirable secondary effects (habituation and dependence). It was not until the nineteenth century that specific synthetic products became available for the control of sleep and anxiety, notably bromine, with its frequent toxic effects (bromism), and chloral. At the beginning of the twentieth century, an important milestone was the discovery of the hypnosedative *barbiturates*.

These derivatives of barbituric acid have since been extensively used for the treatment of insomnia (→ Hypnotics, Chap. 5.1.) and, at lower doses, for anxiety. Some members of this family have potent sedative properties and are still employed as general anesthetics (→ Anesthetics, General). Minor modifications of the barbiturate structure gave the *piperidinedione derivatives* which possess powerful sedative properties (→ Hypnotics, Chap. 5.2.). A further step was made in the mid 1950s with the clinical use of meprobamate, a *propanediol derivative*, for the specific treatment of anxiety. Up until this time, the treatment of sleep problems and anxiety were often confused. Chlordiazepoxide, the first *benzodiazepine* (BZD), was discovered in 1957 and led to a major advance in the treatment of anxiety disorders. The BZDs, which possess power-

ful anxiolytic and sedative properties (see also → Hypnotics, Chap. 5.4.) have superseded the barbiturates, thanks to their greater safety margins and their lower toxicity [156, 157]. Some benzodiazepines (e.g., chlordiazepoxide, clorazepate, or alprazolam) are almost exclusively prescribed as anxiolytics while others (e.g., nitrazepam, flunitrazepam, and triazolam) are exploited for their sedative hypnotic effects. Midazolam is an exception, being used in anesthesiology to induce or maintain narcosis, as premedication before anaesthesia, or during painful or disagreeable procedures which do not merit general anesthesia (endoscopy, biopsies). The consumption of BZDs as anxiolytics or sedatives continued to grow until the end of the 1970s when tolerance and dependence phenomena were reported after prolonged administration. Consumption is now judged to be excessive.

The discovery of compounds with chemical structures different from those of the BZDs, but with anxiolytic or hypnotic potential, was a further important step forward. Anxiolytics normally possess both a sedative and hypnotic action, the latter may be considered as an undesirable secondary effect, especially if diurnal somnolence results. More recent progress offers clinicians anxiolytics without sedative activity. Examples are the BZDs (bretazenil) or the cyclopyrrolones (RP 59037) [158]. Buspirone (an azaspirodecanedione) is a case apart [159] and is already available as a nonsedative anxiolytic (see page 41).

Animal tests for anxiety can be classified in three groups:

1) Tests based on conflict or conditioned fear: since the first experiments of GELLER and SEIFTER in 1960 [160], anxiolytics have been administered to animals to restore certain behavioral responses previously suppressed by punishment
2) Tests based on anxiety generated by novel environments or situations: the social interaction test and the elevated plus-maze test in which BZDs are active as anxiolytic compounds
3) Tests in which anxiety is induced by chemical agents: BZDs antagonize the anxiogenic effects of drugs such as β- carbolines

4.1. Benzodiazepines

Since the early 1960s the study of BZDs has revealed five main pharmacological properties that can be considered characteristic of these anxiolytic – hypnotic drugs: anticonvulsant, myorelaxant, antiaggressive, anxiolytic, and sedative – hypnotic effects [156]. The potency of these pharmacological effects depends on the pharmacokinetics and on the receptor affinity of the tested compound.

Behavioral, biochemical, and electrophysiological studies indicate that these tranquilizing and sedative – hypnotic substances interact with neurotransmission mediated by γ-aminobutyric acid (GABA). BZDs increase the amplitude of the cat dorsal root potential which is mediated by GABA. This increase in amplitude reflects the intensified presynaptic inhibition in the spinal cord [161, 162]. Neurobiochemical research in the domain of the sedative hypnotics has been stimulated by the discovery of specific receptors in the CNS of rats and humans that recognize BZDs with tranquilizing or sedative – hypnotic activity [163, 164]. The so- called BZD receptor consists of at least three different subunits that form a pentameric macromolecular complex, the GABA receptor complex, which constitutes a chloride-permeable ion channel [165–167]. Electrophysiological studies have shown that BZDs increase the frequency at which the chloride channels open and consequently the flux of chloride ions at a given concentration of GABA [157].

4.1.1. 1,4-Benzodiazepines

Chlordiazepoxide [*58-25-3*], 7- chloro-2-methylamino-5-phenyl-3*H*-1,4-benzodiazepine-4-oxide, $C_{16}H_{14}ClN_3O$, M_r 299.75, *mp* 236 –236.5 °C. This first pharmacologically active member of the 1,4-benzodiazepine series is prepared as follows [168]:

Chlordiazepoxide is used in the treatment of anxiety disorders, for the short-term relief of anxiety symptoms, for symptoms of acute alcohol withdrawal, or preoperative apprehension.

Trade Names. Librelease, Libritabs, Librium, Librizan, Tabrium (Roche), Retcol (Towa Yakuhin, Japan), Serendyl (Nezel, Spain), Servium (Teve, Israel), Zeisin (ICN, USA).

Diazepam [*439-14-5*], 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one, $C_{16}H_{13}ClN_2O$, M_r 284.76, *mp* 125–126 °C. Diazepam is prepared as follows [169]:

Use of diazepam is analogous to that of chlordiazepoxide.

Trade Names. Ansiolin (Scharper, Italy), Apozepam (A. L., Norway), Ceregulart (Kaken, Japan), Eurosan (Mepha, Switzerland), Levium (Sodelco, The Netherlands), Paxel (Marion, USA), Stesolid (Dumex, Denmark, CP Pharmaceuticals, UK), Valiquid, Valium, Valrelease (Roche).

Bromazepam [*1812-30-2*], 7-bromo-1,3-dihydro-5-(2-pyridinyl)-2*H*-1,4-benzodiazepin-2-one, $C_{14}H_{10}BrN_3O$, M_r 316.16, *mp* 237–238.5 °C (decomp.). This compound can be synthesized from 2-(2-aminobenzoyl)pyridine in three steps [170]:

Indications are analogous to those of diazepam. Bromazepam, however, seems to be more efficient in the treatment of neurotic anxiety disorders.

Trade Names. Bromazenil (Hexal, Germany), Compendium (Polifarma, Italy), Creosedin (Osiris, Argentina), Durazanil (Durachemie, Germany), Lectopam, Lexomil, Lexotan, Lexotanil (Roche), Normoc (Merckle, Germany).

Lorazepam [*846-49-1*], 7-chloro-5-(2-chlorophenyl)-1,3-dihydro-3-hydroxy-2*H*-1,4-benzodiazepin-2-one, $C_{15}H_{10}Cl_2N_2O_2$, M_r 321.16, *mp* 166–168 °C. Lorazepam is prepared as follows [171].

This short-acting compound is prescribed for management of anxiety disorders or anxiety associated with depressive symptoms.

Trade Names. Almazine (Steinhard, UK), Ativan (Wyeth), Emotival (Armstrong, Argentina), Lorasolid (Dumex, Denmark), Lorax (Wyeth), Pro Dorm (Schürholz, Germany), Tavor (Wyeth), Temesta (Ferrosan, Germany; Wyeth), Wypax (Yamanouchi, Japan).

Oxazepam [*604-75-1*], 7-chloro-1,3-dihydro-3-hydroxy-5-phenyl-2*H*-1,4-benzodiazepin-2-one, $C_{15}H_{11}ClN_2O_2$, M_r 286.74, *mp* 205 – 206 °C. A synthetic pathway analogous to that of lorazepam leads to oxazepam [172].

This short-acting compound is prescribed for the short-term relief of anxiety symptoms. Anxiety associated with depression as well as management of anxiety, tension, agitation, and irritability in the elderly are also responsive to oxazepam therapy. This compound is sometimes used as an hypnotic.

Trade Names. Limbial (Chiesi, Italy), Noctazepam (Brenner, Germany), Praxiten, Serax, Serenid, Seresta (Wyeth), Propax (Cipan, Portugal), Serepax (Wyeth, Ferrosan, Denmark), Sobril (Kabi Vitrum, Sweden), Zaxopam (Quantum, USA).

Clorazepate [*57109-90-7*], 7-chloro-2,3-dihydro-2,2-dihydroxy-5-phenyl-1*H*-1,4-benzodiazepine-3-carboxylic acid, dipotassium salt, $C_{16}H_{11}ClK_2N_2O_4$, M_r 408.93. This compound (used as its dipotassium salt) is prepared as follows [173]:

It is suitable for the symptomatic relief of acute alcohol withdrawal or, as adjunctive therapy, in the management of partial seizures.

Trade Names. Belseren (Mead-Johnson), Mendon (Dainippon, Japan), Transene, Tranxilium (Clin-Midy, France), Tranxène (Abbott, USA; Boehringer Ingelheim, Germany; Clin-Comar-Byla, France), Tranxilène (Clin-Comar-Byla, France).

Prazepam [*2955-38-6*], 7-chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one, $C_{19}H_{17}ClN_2O$, M_r 324.83, *mp* 145 – 146 °C. Alkylation of desmethyldiazepam using sodium hydride and cyclopropylmethyl bromide affords prazepam [174].

Analogously to diazepam, prazepam is suitable for treating anxiety disorders or short-term relief of anxiety symptoms.

Trade Names. Centrax (Parke Davis), Demetrin (Gödecke, Germany, Substantia, Austria, Parke Davis), Lysanxia (Substantia, France), Prazene (Parke Davis), Trepidan (Sigma Tau, Italy), Vestran (Warner-Chilcott).

Camazepam [*36104-80-0*], 7-chloro-1,3-dihydro-3-(*N,N*-dimethylcarbamoyl)-1-methyl-5-phenyl-2*H*-1,4-benzodiazepinone, $C_{19}H_{18}ClN_3O_3$, M_r 371.82, *mp* 173–174 °C. Camazepam is prepared as follows [172,175]:

Trade Names. Albego (Boehringer Ingelheim; Farmasimes, Spain; Inpharzam, Switzerland), Limpidon, Nebolan.

Etizolam [*40054-69-1*], 1-methyl-6-(2-chlorophenyl)-8-ethyl-4*H*-*s*-triazolo[3,4-*c*]thieno-[2,3-*e*]-1,4-diazepine, $C_{17}H_{15}ClN_4S$, M_r 342.85, *mp* 147–148 °C. Treatment of the starting thienodiazepin-2-one with phosphorus pentasulfide in pyridine affords the 2-thione derivative which, by subsequent reaction with hydrazine, yields the 2-hydrazino compound. Final cyclization with azeotropic removal of water gives etizolam [176].

Trade Names. Depas (Yoshitomi, Japan), Pasaden (Farmades, Italy).

Adinazolam [*37115-32-5*], 8-chloro-1-(dimethylamino)methyl-6-phenyl-4*H*-*s*-triazolo-[4,3-*a*]-1,4-benzodiazepine, $C_{19}H_{18}ClN_5$, M_r 351.84, *mp* 165–166 °C. A synthesis of adinazolam starting from nonbenzodiazepine intermediates has been developed. The key step is the conversion of an aminoquinazoline into a benzophenone bearing a potential triazole ring [177].

Trade Name. Deracyn (Upjohn).

Alprazolam [*28981-97-7*], 8-chloro-1-methyl-6-phenyl-4*H*-*s*-triazolo[4,3-*a*]-1,4-benzodiazepine, $C_{17}H_{13}ClN_4$, M_r 308.77, *mp* 228–228.5 °C. Alprazolam can be prepared as follows [178]:

This anxiolytic is less sedative than diazepam, and is useful in the treatment of anxiety associated with depression.

Trade Names. Constan (Takeda, Japan), Frontal, Solanax, Tafil, Trankimazin, Xanax, Xanor (Upjohn), Valeans (Valeas, Italy).

Ketazolam [*27223-35-4*], 11-chloro-8,12*b*-dihydro-2,8-dimethyl-12*b*-phenyl-4*H*-1,3-oxazino[3,2-*d*][1, 4]benzodiazepine-4,7(6*H*)-dione, $C_{20}H_{17}ClN_2O_3$, M_r 368.82, *mp* 182–183.5 °C. Ketazolam is prepared in a one-step synthesis [179]:

This compound is used as an anxiolytic with a long-term effect.

Trade Names. Anseren (Ciba-Geigy, Switzerland), Ansieten (Exa, Argentina), Anxon, Loftram, Sedotime (Beecham), Marcen, Parcil (Antibioticos, Spain), Unakalm (Upjohn).

Clotiazepam [*33671-46-4*], 5-(2-chlorophenyl)-7-ethyl-1,3-dihydro-1-methyl-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-one, $C_{16}H_{15}ClN_2OS$, M_r 318.82, *mp* 105–106 °C. 2-Amino-3-(2-chlorobenzoyl)-5-ethylthiophene, prepared by reaction of butyraldehyde with 2-chloro-1-cyanoacetophenone and sulfur in the presence of triethylamine as catalyst, can be converted to the corresponding aminoacetamide derivative via two methods (Fig. 3) [180]:

This derivative is an anxiolytic thienodiazepine with apharmacological profile analogous to diazepam.

Trade Names. Clozan (Roerig, Belgium), Distensan (Esteve, Spain), Rize (Yoshitomi, Japan), Rizen (Puropharma, Italy), Tienor (Farmaka, Italy), Trecalmo (Tropon, Germany), Veretran (Latéma, France).

Bentazepam [*29462-18-8*], 1,3,6,7,8,9-hexahydro-5-phenyl-2*H*-1-benzothieno[2,3-*e*]-1,4-diazepin-2-one, $C_{17}H_{16}N_2OS$, M_r 296.38, *mp* 251–253 °C, can be prepared as follows [181]:

Trade Name. Thiadipone (C.S.I.C., Spain).

Halazepam [*23092-17-3*], 7-chloro-1,3-dihydro-5-phenyl-1-(2,2,2-trifluoroethyl)-2*H*-1,4-benzodiazepin-2-one, $C_{17}H_{12}ClF_3N_2O$, M_r 352.75, *mp* 164–166 °C. Halazepam is prepared as shown in Figure 4 [182].

This polyfluoroalkyl analogue of diazepam exhibits anxiolytic activity through its metabolite *N*-desmethyldiazepam. This benzodiazepine has a long-lasting effect and is prescribed for treatment of anxiety disorders.

Figure 3. Synthesis of clotiazepam

Trade Names. Alapryl (Menarini, Spain), Pacinone (Delagrange, Belgium), Paxipam (Schering Corp., UK).

Figure 4. Synthesis of halazepam

4.1.2. Other Benzodiazepines

Tofisopam [*22345-47-7*], 7,8-dimethoxy-1-(3,4-dimethoxyphenyl)-5-ethyl-4-methyl-5*H*-2,3-benzodiazepine, $C_{22}H_{26}N_2O_4$, M_r 382.46, *mp* 156 – 157 °C. This 2,3-benzodiazepine is prepared as follows [183]:

Tofisopam exhibits anxiolytic activity without the classical side effects of 1,4-benzodiazepines (hypnotic, anticonvulsant, myorelaxant effects) and does not affect the psychological faculties.

Trade Names. Grandaxin (Egis, Hungary; Ozothine, France), Sériel (Fabre, France), Tavor (Gerardo Ramon, Argentina).

Clobazam [*22316-47-8*], 7-chloro-1-methyl-5-phenyl-1*H*-1,5-benzodiazepine-2,4(3*H*,5*H*)-dione, $C_{16}H_{13}ClN_2O_2$, M_r 300.74, *mp* 180 – 182 °C. Clobazam is prepared as follows [184]:

Trade Names. Clarmyl (Roussel-Iberica, Spain), Frisin, Frisium, Karidium, Noiafren, Sentil (Hoechst), Urbadan, Urbanol (Roussel), Urbanyl (Diamant, France, Roussel).

4.2. Carbamates

Meprobamate [*57-53-4*], 2-methyl-2-propyl-1,3-propyldicarbamate, $C_9H_{18}N_2O_4$, M_r 218.25, *mp* 104 – 106 °C. Meprobamate is prepared as follows [185]:

Meprobamate is an anxiolytic agent which has anticonvulsant, myorelaxant, and sedative properties [160], but it does not directly interfere with the GABA-receptor complex. The potentiation of the release of adenosine by meprobamate may account for its central effects [186]. This carbamate derivative has been used for the management of anxiety disorders and tension states but has been superseded by benzodiazepines.

Trade Names. Amosene (Ferndale, USA), Artolon (Roter, The Netherlands), Cyrpon (Tropon, Germany), Equanil (Wyeth, Clin-Comar-Byla, France), Miltaun (Mack, Germany), Perequil (Merrell Dow Lepetit), Aneural, Quaname, Quanil (Wyeth), Tranquilin (SAM-Parke-Davis, Belgium).

Phenprobamate [*673-31-4*], 3-phenylpropyl carbamate, $C_{10}H_{13}NO_2$, M_r 179.21, *mp* 101 –104 °C, for preparation see [187].

It has been given as an anxiolytic and myorelaxant.

Trade Names. Actiphan (Teikoku, Nagase, Japan), Ansepron (Fuso, Japan), Gamaquil (Siegfried, Switzerland; Leo, Mekos, Pharmacia, Sweden), Kuilil (Embil, Turkey), Nelaxan (Toho, Japan), Paraquick (Ohta, Japan), Phencol (Towa Yakuhin, Japan), Spantol (Nippon Chemiphar, Japan).

Tybamate [*4268-36-4*], *N*-butyl-2-methyl-2-propyl-1,3-propyldicarbamate, $C_{13}H_{26}N_2O_4$, M_r 274.35, *mp* 49 – 51 °C, is prepared by reaction of 2-methyl-2-propyl-3-hydroxypropyl carbamate with butyl isocyanate [188].

Trade Name. Tybatran (Robins, USA).

Hydroxyphenamate [*50-19-1*], 2-hydroxy-2-phenylbutyl carbamate, $C_{11}H_{15}NO_3$, M_r 209.24, *mp* 55 – 56.5 °C. This carbamate is prepared from β-ethyl-β-hydroxyphenethyl alcohol and ethyl chloroformate followed by reaction with ammonia [189].

Trade Name. Listica (Armour).

4.3. Other Anxiolytics

Hydroxyzine [*68-88-2*], 2-{2-{4-[(4-chlorophenyl)phenylmethyl]-1-piperazinyl}ethoxy}-ethanol, $C_{21}H_{27}ClN_2O_2$, M_r 374.92, *mp* 193 °C. Hydroxyzine is produced as follows [190]:

Hydroxyzine is an antihistaminic diarylalkylpiperazine which is used as an anxiolytic. It has no cortical depressant activity, its anxiolytic action could be explained by its suppressive effect on neuronal activity in subcortical areas. A myorelaxant activity has also been demonstrated experimentally.

Trade Names. (Dihydrochloride) Alamon (Grelan, Japan), Atarax (Pfizer, Belgium; UCB-Fraysse, France), Aterax (UCB, Belgium), Multipax (Rorer, USA), Orgatax (Organon), Ulgrax (UCB, Belgium), Vistaril Parenteral (Pfizer), (Pamoate) Equipose (Pfizer).

Etifoxine [*21715-46-8*], 6-chloro-2-ethylamino-4-methyl-4-phenyl-4*H*-3,1-benzoxazine, $C_{17}H_{17}N_2O$, M_r 300.79, *mp* 90 °C, hydrochloride, *mp* 150 °C. Etifoxine is produced as follows [191]:

In rodents, etifoxine proved to be an anxiolytic. It possesses sedative, antiaggressive, anticonvulsant, and anticonflict effects [192]. Etifoxine enhances GABA-mediated neurotransmission.

Trade Name. (Chloride) Stresam (Beaufour, France).

Alpidem [*82626-01-5*], 6-chloro-2-(4-chlorophenyl)-*N,N*-dipropylimidazo[1,2-*a*]pyridine-3-acetamide, $C_{21}H_{23}Cl_2N_3O$, M_r 404.34, *mp* 140–141 °C. Alpidem is produced as follows [193]:

Alpidem is an imidazopyridine derivative which produces anxiolytic-like effects in some but not all models and anticonvulsant properties without myorelaxant and sedative effects [194].

Whereas BZDs are largely nonselective for the subtypes of the GABA receptor complex, alpidem displays a preferential affinity for the BZD_1 modulatory site [195]. Moreover, relatively high doses of alpidem antagonize the myorelaxant and sedative – hypnotic activities of diazepam.

Trade Name. Ananxyl (Synthelabo, France).

Buspirone [*36505-84-7*], 8-[4-[4-(2-pyrimidinyl)-1-piperazinyl]butyl]-8-azaspiro[4.5]decane-7,9-dione, $C_{21}H_{31}N_5O_2$, M_r 385.51, hydrochloride, *mp* 202 °C, is prepared as follows [196]:

In tests for predicting clinical anxiolytic activity, buspirone, an azaspirodecanedione derivative, attenuates conflict behavior in pigeons, rodents, and monkeys. Buspirone is less sedative than the classical BZDs as shown in experimental and clinical trials. It is ineffective as an anticonvulsant against convulsions induced by pentylenetetrazol, bicuculline, picrotoxine, or supramaximal electroshock. Similarly, no motor incoordination or myorelaxant activity occurs in buspirone-treated animals [195].

Buspirone does not bind to the GABA receptor complex and does not affect BZD binding. Its most evident interaction occurs at the $5\text{-}HT_{1A}$ receptor. This action is supported by binding studies, anatomical localization, neurochemistry, electrophysiology, and animal behavior [197].

Trade Names. Anisal (Vita, Spain), Ansiced (Abello, Spain), Bespar (Bristol), Buspar (Astra, Bristol-Myers, Mead-Johnson), Buspisal (Lesvi, Spain), Buspon (Deva, Turkey), Censpar (Bristol-Myers), Noral (Almirall, Spain).

4.4. Anxiolytics Under Development

New agents have been reported which interact with the central BZD receptor complex, but do not have a simple benzodiazepine structure. They appear to be selective in their anti-anxiety action. Examples include bretazenil, abecarnil, FG-7516, CGS 20625, and dipavlon. *Bretazenil* [*84379-13-5*] (Ro 166028-Roche) exhibits anticonflict and anticonvulsant properties. Only mild sedation appears at doses needed to produce anticonvulsant or anxiolytic effects, and potentiation of ethanol-induced sedation is less pronounced than with diazepam. Unlike full agonists, physical dependence could not be induced in monkeys after administration of bretazenil, even at a very high dose. Bretazenil is a partial agonist at the GABA-A receptor complex. It is in clinical trials (phase III) for generalized anxiety disorders, panic attacks, and schizophrenia [198]. *Abecarnil* [*111841-85-1*] [199] (ZK 112119, Schering) belongs to the β-carboline family and is in phase III clinical trials. It is active as an anxiolytic but less sedative or myorelaxant than diazepam. Like bretazenil, abecarnil must be considered as a partial agonist at the GABA-A receptor complex. *FG-7516* [*83910-44-5*] (Novo-Nordisk) is structurally related to abecarnil and is also in phase III clinical trials [200].

CGS-20625 [*111205-55-1*] is undergoing phase I clinical trials as a potent, selective inhibitor at the central benzodiazepine receptor. It does not appear to have the side effects of diazepam. This analogue of CGS-9895 (suspended) belongs to the cyclohepta[*b*]pyrazolo[3,4-*d*]pyridin-3(2*H*)-one family. *Dipavlon* [*90808-12-1*] (RU 32698, Roussel-Uclaf) is an imidazo[1,2-*a*]pyrimidine with anticonvulsant and anxiolytic properties but with few effects in tests used to predict sedation or motor impairment in rodents. Anxiolytic

and anticonvulsant effects are antagonized by flumazenil, the BZD antagonist. Dipavlon acts as a partial agonist at the GABA-A receptor complex and is in phase II clinical trials.

Suriclone [*53813-83-5*] (Rhône-Poulenc Rorer) is a cyclopyrrolone derivative which acts at the GABA-A receptor complex. It does not induce physical dependence in mice even at a high dose after a chronic treatment. Binding studies show that suriclone interacts with a different binding domain to anxiolytic BZD. Clinical studies have shown that suriclone is an anxiolytic with a low incidence of drowsiness and a low dependence potential compared with BZD.

The discovery of the anxiolytic properties of the 5-HT_{1A} partial agonist buspirone has given rise to a second generation of serotoninrgic agents (e.g., gepirone, ipsapirone, tandospirone, umespirone, zalospirone, and metanopirone). All these agents are, however, of low efficacy in patients having been treated with BZDs (lack of muscle relaxant and sedative properties). Other serotoninrgic agents such as ritanserin (5-HT_2 antagonist) or ondansetron (5-HT_3 antagonist) are effective in the treatment of generalized anxiety disorders [201].

Among newer molecular approaches to anxiety, selective antagonists such CI 988 or L 365,260, for the brain cholecystokinin receptors as well as the angiotensin II antagonist DuP 753 have been reported to be potential anxiolytics [202, 203].

5. Geriatric Drugs

Geriatric drugs include substances with cognition-enhancing properties that are used to treat the mental manifestations of aging. The continual increase in the expected lifespan in developed countries enhances the prevalence of conditions ranging from mild age-associated memory impairments (AAMI) to senile dementias (SD). Neurodegenerative processes and atherosclerosis have been identified as possible etiologic causes for certain types of dementias such as senile dementias of the Alzheimer's type (SDAT) and multi-infarct dementia.

The search for geriatric drugs is characterized by the absence of unequivocal clinically effective reference compounds. Moreover, inability to identify neurobiological processes that are specifically involved in memory formation in the brain makes the preclinical evaluation of these compounds difficult. Behavioral models of learning based on cognitive interpretations of rodent locomotor performances often remain the only available testing procedure [204].

Although no currently available drug can stop the evolution of cognitive disorders, this chapter focuses on important drugs that alleviate or correct some of the symptoms of the disease.

5.1. Nootropics

The term nootropic denotes substances that do not act through a given neurotransmitter system, that are neither psychostimulant nor sedative, and that improve learning performance or compensate for learning deficits induced by amnesic manoeuvres in behavioral models. Although a number of geriatric drugs fall within this rather wide unrestrictive definition, the classical nootropics are chemically related to their prototype piracetam (2-pyrrolidinone derivatives). Their mechanism of action is not known, although they are believed to act in the telencephalon [205]. The toxicity of nootropics is generally low.

Piracetam [*7491-74-9*], 2-oxo-1-pyrrolidineacetamide, $C_6H_{10}N_2O_2$, M_r 142.16, *mp* 151 – 152 °C is prepared by condensing 2-pyrrolidinone with ethyl chloroacetate in the presence of a metal hydride and then converting the ester into an amide with ammonia [206].

Piracetam protects the brain from hypoxic insults and facilitates transcallosal synaptic transmission in animals. In addition to senile dementia, it is proposed for the treatment of dyslexia in children and of cerebrovascular stroke.

Trade Names. Agivilen (Efeka, Germany), Ciclofalina (Almirall, Spain), Durapitrop (Durachemie, Switzerland), Noostan (UCB, Belgium), Nootrop (UCB, Belgium), Novocetam

(Beiersdorf, Germany), Piracebral (Hexal, Germany), Stimucortex (Kalifarma, Spain).

Aniracetam [*72432-10-1*], 1-(4-methoxybenzoyl)-2-pyrrolidone, $C_{12}H_{13}NO_3$, M_r 219.24, *mp* 121 – 122 °C is prepared by condensing 2-pyrrolidone with 4-methoxybenzoyl chloride [207].

This piracetam-related cognition enhancer reduces glutamate receptor desensitization [208].

Trade Names. Draganon (Roche, Switzerland), Sarpul (Toyama, Japan).

Oxiracetam [*62613-82-5*], 4-hydroxy-2-oxo-1-pyrrolidineacetamide, $C_6H_{10}N_2O_3$, M_r 158.16, *mp* 165 – 168 °C. Oxiracetam can be prepared as follows [209]:

A second route starts with 4-amino-3-hydroxybutyric acid which is *O*-silylated and dehydrated to give 2-oxo-3-trimethylsilyloxypyrrolidine. Alkylation with ethyl bromoacetate, deprotection of the alcohol, and ammonolysis afford oxiracetam.

Oxiracetam is more hydrophilic than aniracetam and is claimed to have a wider therapeutic spectrum.

Trade Names. Neupan (SmithKline Beecham, Portugal), Neuractiv (Ciba-Geigy, Switzerland), Neuromet (ISF, Italy).

5.2. Cholinergic Drugs

Cholinergic drugs are used in cognitive disorders on the assumption that they compensate for the deficiency of central cholinergic processing that is thought to underly dementia [210]. This cholinergic hypothesis is supported by results from learning experiments which show that antagonists at muscarinic receptors (e.g., scopolamine) induce impairment in animals and humans. Destruction of the principal cholinergic projection system in the rodent brain produces similar effects, and a loss of cholinergic terminals has been observed in the brains of patients suffering from Alzheimer's disease.

5.2.1. Choline Analogues

Choline analogues or choline-containing precursors are used in an attempt to increase the rate of brain acetylcholine synthesis. These compounds are expected to be more effective than simple dietary supplementation with choline or choline-containing lecithin.

Deanol [*108-01-0*], 2-(dimethylamino)ethanol, $C_4H_{11}NO$, M_r 89.14, *bp* 135 °C, is prepared from dimethylamine and ethylene oxide [211]. It also exists as the salts of acetylglutamic, 4-acetamidobenzoic, succinic, and tartaric acids.

Deanol is metabolized and incorporated into the brain choline pool, thereby increasing choline availability [212]. This compound may also have an effect on brain phospholipid metabolism.

Trade Names. Acumen (Menarini, Spain), Bimanol (Polfa, Poland), Cervoxan (S.M.B., Belgium), Deaner (Riker), Diforène (Choay, France), Pabenol (Gentili, Italy), Tonibral (Bouchara, France), Varesal (Arzneimittelwerk, Germany).

Meclofenoxate [*51-68-3*], dimethylaminoethyl 4- chlorophenoxyacetate, $C_{12}H_{16}Cl_2NO_3$, M_r 293.22, *mp* 135 – 139 °C. Meclofenoxate is obtained by condensing 4- chlorophenoxyacetyl chloride with 2-(dimethylamino)ethanol [213].

Trade Names. Analux (Polfa, Poland), Brenal (Tanabe, Japan), Cerutil (Arzneimittelwerk, Germany), Helfergin (Promonta, Germany), Marucotol (Maruko, Japan), Mecloxate (Sawai, Japan), Proseryl (Funai, Japan), Ropoxyl (Nippon Chemiphar, Japan).

Citicoline [*987-78-0*], cytidine 5′-sodium diphosphate choline ester, $C_{14}H_{25}N_4NaO_{11}P_2$, M_r 456.33, is a nucleotide coenzyme that plays an important role in the metabolism of phospholipids. It is prepared by reacting choline phosphate and cytidine 5′-phosphate with a condensation reagent such as *N,N′*-dicyclohexylcarbodiimide [214] or tosyl chloride [215].

Trade Names. Alaton (Zambon, Italy), Colite (Nippon Chemiphar, Japan), Corenalin (Kaken, Japan), Ensign (Yamanouchi, Japan), Eumetabol (Llano, Spain), Nicholin (Takeda, Japan; Byk Procienx, Brazil), Nicolsint (Von Boch, Italy), Nicolin (Morishita, Japan), Startonyl (American Cyanamid, USA).

5.2.2. Cholinesterase Inhibitors

Cholinesterase inhibitors are used with the rationale that they can increase the efficiency of the remaining cholinergic terminals by inhibiting acetylcholine depletion.

Physostigmine [*57-47-6*], (3*aS*- *cis*)-1,2,3,3*a*, 8,8*a*-hexahydro-1,3*a*,8-trimethylpyrrolo[2,3-*b*]-indol-5-ol methyl carbamate, $C_{15}H_{21}N_3O_2$, M_r 275.34, *mp* 105 – 106 °C, is extracted from calabar beans [216].

Physostigmine restores learning performance in animals with lesions of the nucleus basalis magnocellularis [217].

Trade Names. Anticholium (Köhler, Germany), Antilirium (Forest, USA), Fiostin (Tubi Lux Farma, Italy).

Tacrine [*321-64-2*], 9-amino-1,2,3,4-tetrahydroacridine, $C_{13}H_{14}N_2$, M_r 198.27, *mp* 183 – 184 °C, can be prepared by different methods, the shortest is condensation of 2-aminobenzonitrile with cyclohexanone [218].

This product is a known curare antidote. It has a longer half-life than physostigmine and has been used with some success by oral route in Alzheimer's patients [219]. Tacrine competitively inhibits acetylcholinesterase and also modifies the resting conductance and responses of neurons in the hippocampus.

Trade Name. Cognex (Warner Lambert).

5.2.3. Thyroliberin Analogues

Thyroliberin, also known as thyrotropin releasing hormone (TRH), is a hypothalamic regu-

latory hormone. It also acts on cholinergic neurons to enhance high affinity choline uptake and stimulate acetylcholine synthesis and release. See also → Peptide and Protein Hormones, Chap. 2.2. Thyroliberin is of possible interest for the treatment of neurodegenerative processes, such as Alzheimer's disease and amyotrophic lateral sclerosis.

Protirelin [*24305-27-9*], 5-oxo-L-prolyl-L-histidyl-L-prolinamide, $C_{16}H_{22}N_6O_4$, M_r 362.39, the natural TRH tripeptide is prepared by conventional peptide synthesis [220].

Trade Name. Hirtonin (Hoechst).

Posatirelin [*78664-73-0*], L-pyro-2-aminoadipyl-L-leucyl-L-prolinamide, $C_{17}H_{28}N_4O_4$, M_r 352.44, *mp* 214–216 °C, is prepared by sequential coupling, amino acids being activated as their pentafluoro esters. Prolinamide is condensed with *N*-carboxybenzylleucine. The dipeptide is then deprotected and coupled with L-pyro-2-aminoadipic acid [221].

Posatirelin is a pseudopeptide which improves sequelae of head injury and subarachnoid hemorrhage.

Trade Name. Pyladox (Dainippon).

5.3. Metabolically Active Drugs

Metabolically active drugs are heterogeneous compounds with different proposed mechanisms of action. They help to restore deficient brain energy metabolism. Some of the most prescribed cognition enhancers are members of this class.

Idebenone [*58186-27-9*], 2,3-dimethoxy-6-(10-hydroxydecyl)-5-methyl-1,4-benzoquinone, $C_{19}H_{30}O_5$, M_r 338.45, *mp* 46–50 °C, is prepared in five steps. Friedel–Crafts acylation of 3,4,5-trimethoxytoluene with 1,10-decanedioic acid semiester affords a partially demethylated keto acid which is esterified and then reduced twice. The phenolic ring is oxidized with Fremy's salt to give the quinone [222].

Idebenone is a benzoquinone that is derived from the widely distributed ubiquinones. It accelerates ATP formation by activating the electron-transfer system. It has free-radical scavenger properties, stimulates mitochondrial respiration, and reduces membrane lipid peroxidation.

Trade Names. Aban, Avan (Takeda, Japan).

Nicergoline [*27848-84-6*], 5-bromo-3-pyridinecarboxylate (8*β*)-1,6-dimethyl-10-methoxyergoline-8-methanol, $C_{24}H_{26}BrN_3O_3$, M_r 484.40, *mp* 136–138 °C, is prepared by reducing a lumilysergic acid derivative with $LiAlH_4$ and acylating the alcohol thus obtained with 5-bromo-3-pyridinecarboxylic acid chloride [223].

Trade Names. Duracebrol (Durachemie, Germany), Ergobel (Hormosan, Germany), Memoq (Gödeke, Germany), Nicergolyn

(Farnex, Italy), NicerHexal (Hexal, Germany), Sermion (Farmitalia Carlo Erba; Specia), Varson (Almirall, Spain).

Ergoloid mesylates, also called dihydroergotoxine or co-dergocrine, is a mixture of the hydrogenated ergot alkaloids dihydroergocornine [*25447-65-8*], dihydroergocristine [*17479-19-5*], and dihydro-α-ergocryptine [*25447-66-9*], and dihydro-β-ergocryptine [*77528-01-9*].

Dihydroergotoxine is among the most widely prescribed geriatric drugs. It has vasoactive properties and increases brain oxygen tension and electrical activity [224].

Trade Names. Circanol (Riker), Deapril-ST (Mead Johnson), Hydergine (Sandoz), Niloric (Ascher), Trigot (Squibb).

Dihydroergocornine	R = $CH(CH_3)_2$
Dihydroergocristine	R = $CH_2C_6H_5$
Dihydro-α-ergocryptine	R = $CH_2CH(CH_3)_2$
Dihydro-β-ergocryptine	R = $CH(CH_3)CH_2CH_3$

Bifemelane [*90293-01-9*], 2-(4-methylaminobutoxy)diphenylmethane, $C_{18}H_{23}NO$, M_r 269.39, *mp* 117 – 121 °C, is prepared by alkylation of 2-hydroxydiphenylmethane with 1,4-dibromobutane and subsequent condensation with methylamine [225].

Bifemelane has antianoxic and anti-ischemic properties. It also exerts an indirect cholinomimetic effect by increasing acetylcholine release [226].

Trade Names. Alnert (Mitsubishi, Japan), Celeport (Esai, Japan).

Vinpocetine [*42971-09-5*], $C_{22}H_{26}N_2O_2$, M_r 350.46, *mp* 147 – 153 °C is prepared by esterification of vincaminic acid [227].

Vinpocetine is a Vinca alkaloid. It increases cerebral blood flow and glucose utilization, and inhibits brain edema formation produced by cerebral metabolic inhibitors [224].

Trade Names. Cavinton, Ceractin (Ayerst), Eusenium (Thiemann, Germany).

Propentofylline [*55242-55-2*], 3,7-dihydro-3-methyl-1-(5-oxohexyl)-7-propyl-1*H*-purine-2,6-dione, $C_{15}H_{22}N_4O_3$, M_r 306.37, *mp* 69 – 70 °C, is prepared by reacting 3-methyl-7-propylxanthine with 6-bromo-2-hexanone in refluxing sodium hydroxide [228].

This alkylxanthine is structurally related to the naturally occurring psychostimulant caffeine (methylxanthine). Propentofylline inhibits cyclic nucleotide phosphodiesterases, thereby increasing the levels of intracellular second messengers [229].

Trade Name. Hextol (Hoechst, Japan).

Pyritinol [*1098-97-1*], bis(4-hydroxymethyl-5-hydroxy-6-methyl-3-pyridylmethyl)-disulfide, $C_{16}H_{20}N_2O_4S_2$, M_r 368.48, *mp* 218 – 220 °C, is prepared by reacting a salt of 3,4-bis(bromomethyl)-5-hydroxy-6-methylpyridine with potassium xanthogenate and then hydrolyzing the intermediate with alcoholic ammonia [230].

Pyritinol consists of two pyridoxine (vitamin B_6) molecules linked by a disulfide bridge. It is devoid of vitamin B_6-like activity and improves glucose metabolism in patients with organic brain disorders based on disturbed cerebral glucose metabolism [231].

Trade Names. Bonifen (Merck, Spain), Dinerfene (Azevedos, Spain), Divalvon-D (Nippon Kagaku, Japan), Enbol (Merck, Japan), Encefavol (Bracco, Italy), Neuroxin (Yamanouchi, Japan), Sawaxin (Sawai, Japan).

5.4. Antidepressants

Several atypic antidepressants that lack the anticholinergic activity of classical tricyclic antidepressants are successfully used in the treatment of cognitive disorders. Their activity may also be due to the alleviation of depression which often contributes to a decline in cognitive performance in the elderly patient.

Citalopram (see Section 3.4) inhibits 5-HT reuptake and significantly improves cognitive performance in Alzheimer patients [134].

Exifone [*52479-85-3*], 2,3,3′,4,4′,5′-hexahydroxybenzophenone, $C_{13}H_{10}O_7$, M_r 278.22, *mp* 270 °C, is prepared by the Friedel–Crafts acylation of pyrogallol with 3,4,5-trihydroxybenzoic acid [232].

Exifone shows an atypical antidepressant profile of activity in a range of standard psychopharmacological tests [233] and is also claimed to protect against hypoxia. This metabolic enhancer has no anticholinergic properties and thus lacks associated side effects.

Trade Name. Adlone (Pharmascience, France).

Indeloxazine [*65043-22-3*], 2-[(inden-7-yloxy)methyl]morpholine hydrochloride, $C_{14}H_{18}ClNO_2$, M_r 267.76, *mp* 155–156 °C, is prepared as follows [234]:

The two isomers are separated by fractional crystallization [234].

This antidepressant agent inhibits 5-HT and noradrenaline reuptake but has only weak effects on neurotransmitter receptors. It is effective in treating neuropsychological symptoms, the major side effect being gastrointestinal disorders.

Trade Names. Elen, Noin (Essex Nippon, Yamanouchi, Japan).

5.5. Miscellaneous Geriatric Drugs

Phosphatidylserine is extracted from bovine cerebral cortex. It is believed to act on neuronal membrane fluidity and acetylcholine release. It improves learning performance in aged rats [235].

Trade Name. Bros (Fidia).

Acetylcarnitine [*5080-50-2*], $C_9H_{18}ClNO_4$, M_r 239.70, *mp* 187 °C, is an endogeneous substance. It is prepared by acetylation of L-carnitine [236].

Acetyl-L-carnitine stereospecifically facilitates neuronal electrophysiological responses to acetylcholine and 5-HT [237].

Trade Names. Branigan (Glaxo, Italy), Nicetile (Sigma-Tau, Italy).

Nimodipine [*66085-59-4*], isopropyl 2-methoxyethyl 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-3,5-pyridinedicarboxylate, $C_{21}H_{26}N_2O_7$, M_r 418.45, *mp* 125 °C, is prepared as follows [238]:

Nimodipine is a calcium channel antagonist used for its vasodilatatory and hemodynamic effects on cerebral blood vessels [239].

Trade Name. Nimotop (Bayer).

5.6. Geriatric Drugs Under Development

The search for cognition enhancers is a rapidly growing field and numerous substances are being investigated. The following are in the phase III stage of development. *Sabeluzole* [*104592-54-3*] (R 58735) is a benzothiazole derivative under investigation by Janssen. It has antihypoxic and anticonvulsant properties [240]. *Denbufylline* [*57076-71-8*] (BRL-30892, Smith K-line Beecham) is an alkylxanthene derivative which shares the phosphodiesterase-inhibiting properties of this class of drugs [224]. It is under investigation in multi-infarct dementia. *Pramiracetam* [*68497-62-1*] (CI-879) is a nootropic closely related to piracetam under development by Parke-Davis for memory and cognitive deficits following electroconvulsive shock therapy. *Teniloxazine* [*62473-79-4*] (Y-8894) is a nonpyrrolidine nootropic compound developed by Yoshitomi which has also antiulcer properties in the gastrointestinal tract. *Velnacrine* [*118909-22-1*] (HP-029, Hoechst-Roussel) is an analogue of tacrine with cholinesterase-inhibiting properties. It is under clinical investigation in Alzheimer's patients. *Vinconate* [*70704-03-9*] (OC-340, Omnichem) increases brain oxygen levels and delays the onset of EEG abnormalities during hypobaric hypoxia in humans.

1. Introduction

Purine [*120-73-0*], 7*H*-imidazo[4,5-*d*]pyrimidine, M_r 120.12, is a bicyclic molecule composed of the fused heterocycles imidazole and pyrimidine.

The name purine (from "purum uricum") as well as the ring-numbering technique still practiced today can be attributed to EMIL FISCHER. Oxygen-containing purine derivatives are often represented in the isomeric lactam form, as with xanthine (**1**):

1

Infrared spectra reveal that oxygen-containing purine derivatives (including hypoxanthine and uric acid) exist mainly as lactams whereas free amine groups can be detected with aminopurines (e.g., adenine) [1]. Purine derivatives with an *N*-methylated pyrimidine ring (e.g., from compounds like xanthine) are also based on the lactam form.

Purines were among the first natural products identified. Thus, in 1776 SCHEELE extracted a substance from urinary calculi which FOURCROY named uric acid (*acide ourique*) in 1793. In 1834, LIEBIG and MITSCHERLICH established its correct empirical formula as $C_5H_4N_4O_3$. RUNGE isolated caffeine from coffee beans in 1820, and in 1844 UNGER isolated guanine from guano. These and other studies led MEDICUS in 1875 to suggest a bicyclic structure for uric acid and its derivatives. Thorough investigations by EMIL FISCHER (1882 – 1897) clarified the relationships linking these compounds, and in 1884 the current name was assigned to the series of substances and the Medicus structure was confirmed. At about the same time A. KOSSEL isolated guanine (1883) and adenine (1885) from nucleic acids. Finally, around the turn of the century, this initial research era was brought to a close with a series of total syntheses by W. TRAUBE [2]. Extensive work was later resumed by BREDERECK [3].

2. Properties

Physical Properties. Purine and its *C*-alkyl derivatives are very soluble in water. Purines containing hydroxyl groups show only poor solubility in water and organic solvents, whereas aminopurines are fairly soluble. With the exception of uric acid, the compounds are amphoteric, yielding water-soluble salts with both acids and bases. The acidic character of purine derivatives increases with the number of hydroxyl groups in the molecule. The dissociation constant of uric acid (pK_a 5.7) is almost comparable to that of aliphatic carboxylic acids; aminopurines, on the other hand, are more basic. The melting points of purines are often very high, and they are of limited use for characterization. Melting points of several purines are listed in Table 1.

Chemical Properties. Purine derivatives undergo nucleophilic substitution at the 2-, 6-, and 8-positions due to delocalization of the pyrimidine and imidazole π-electrons. Appropri-

Table 1. Melting points of representative purines

Common name	Systematic name	CAS registry no.	M_r	*mp*, °C
Purine	7*H*-imidazo[4,5*d*]pyrimidine	[*120-73-0*]	120.1	217
Adenine	6-aminopurine	[*73-24-5*]	135.1	360 – 365 (decomp.)
Guanine	2-amino-6-hydroxypurine	[*73-40-5*]	151.1	365 (decomp.)
Hypoxanthine	6-hydroxypurine	[*68-94-0*]	136.1	
Mercaptopurine	6-mercaptopurine	[*50-44-2*]	152.2	313 – 314 (decomp.)
Thioguanine	2-amino-6-mercaptopurine	[*154-42-7*]	167.2	>360
Xanthine	2,6-dihydroxypurine	[*69-89-6*]	152.1	
3-Methylxanthine		[*1076-22-8*]	165.1	380 (decomp.)
Theophylline	1,3-dimethylxanthine	[*58-55-9*]	179.2	269 – 272
monohydrate		[*5967-84-0*]	197.2	
Theobromine	3,7-dimethylxanthine	[*83-67-0*]	179.2	351
Caffeine	1,3,7-trimethylxanthine	[*58-08-2*]	193.2	234 – 235
monohydrate		[*5743-12-4*]	211.2	
Uric acid	2,6,8-trihydroxypurine	[*69-93-2*]	168.1	

ately activated derivatives are also subject to electrophilic substitution at position 8. Derivatives free of substituents in the 7-position readily yield salts under alkaline conditions (e.g., sodium theophylline). These salts remain very stable to hydrolytic ring cleavage. On the other hand, the pyrimidine ring in 1,3,7-peralkylated xanthines (e.g., caffeine) is highly susceptible to basic cleavage. For more information see [4–6].

3. Occurrence and Production

Purine derivatives are widespread in nature. Adenine and guanine, as components of nucleic acids and nucleosides, are fundamental building blocks of life (→ Nucleic Acids). Purine itself is a component of the *N*-nucleoside nebularine [*550-33-4*] [7], which displays antibiotic properties (→ Antibiotics). *N*-Alkylpurinediones (*N*-alkylxanthines) are also abundant in nature; the most common is caffeine, which occurs in concentrations of 1 – 1.5 % in coffee beans and up to 5 % in black tea leaves, as well as in a number of other plants. Caffeine is isolated by solvent extraction from green coffee beans and tea leaves. The Zosel high-pressure extraction process is a more sophisticated procedure involving supercritical carbon dioxide [8], resulting in mild, selective, and toxicologically safe decaffeination (→ Coffee, Chap. 4.). Another purine, theobromine, is found in cacoa hulls at concentrations of 1.5 – 3 %.

Purine biosynthesis is a multistep enzyme-catalyzed process based on simple building blocks. 5′-Phosphoribosylglycinamide (**2**) is first produced from α-D-ribose and glycine. Subsequent steps lead to the formation of 5′-phosphoribosyl-5-aminoimidazole (**3**), onto which the pyrimidine ring is added, again in a multistep sequence.

The product inosinic acid (**4**) [*131-99-7*] is a starting material for the synthesis of other purine compounds [9].

The final product of human purine metabolism is uric acid (**5**). Thus, adenine (**6**) is converted to xanthine (**1**) via hypoxanthine (**7**).

Guanine (**8**) is converted to **1** directly. Xanthine oxidase then catalyzes oxidation of xanthine to uric acid.

Physical disorders related to purine metabolism include xanthinuria, an inherited metabolic disease caused by the absence of xanthine oxidase, and gout, which leads to deposits in the joints as a result of excessive uric acid concentration in the blood (→ Gout Remedies, Chap. 1.→ Gout Remedies, Chap. 2.→ Gout Remedies, Chap. 3.).

Other organisms are capable of degrading uric acid further to allantoin(most mammals and reptiles),allantoic acid,and ultimately urea(e.g.,fish).

A number of synthetic pathways for purines have been described with such starting materials as hydrocyanic acid or formamide [10], but only moderate yields have been achieved. A prebiotic synthesis based on hydrocyanic acid has also been considered (e.g., for adenine, which is formally a pentamer of HCN) [11]. Industrial processes begin with simple starting materials. A stepwise approach is used to construct either the pyrimidine or imidazole ring, onto which is subsequently fused the second heterocycle. A synthetic approach originally developed by TRAUBE [2] and later subjected to several improvements is well-adapted to the production of the commercially important xanthine derivatives caffeine, theophylline, and theobromine. A series of steps starting with *N,N′*-dimethylurea [12, 13] and cyanoacetic acid leads to theophylline (**9**), which can be methylated to give caffeine (**10**):

The same reaction path starting with monomethylurea [12] yields 3-methylxanthine (**11**), which undergoes preferential methylation to theobromine (**12**).

Other known routes to xanthine derivatives are not utilized commercially, either because the starting materials are expensive or because overall yields are less satisfactory (e.g., syntheses starting from imidazole derivatives, or the direct cyclization of 1,3-dimethyl-6-methylamino-5-nitrosouracil [14]).

Guanine and its derivatives can also be prepared from suitably substituted pyrimidine derivatives [15]. Guanine, adenine, xanthine, and hypoxanthine can be made from appropriate imidazole derivatives [16]:

Purine derivatives are also accessible from arylazomalonic acid derivatives [17]:

4. Quality Specifications and Analysis

Since purine derivatives find their most important use as pharmacological agents, quality standards and analytical practices are subject to the regulations of pharmacopoeia (USP, BP, Ph. Eur., DAB, JP, etc.). The food industry also generally employs materials that comply with the specifications of the pharmacopoeia (e.g., caffeine for soft drinks). Purine derivatives employed as pharmacological agents must be prepared according to current good manufacturing practice (GMP) specifications. Product control must always comply with relevant national laws and international agreements (e.g., the Pharmaceutical Inspection Convention). Purity control by thin layer chromatography, customary in the past, is increasingly being replaced by high-pressure liquid chromatography.

5. Uses

Due to their broad spectrum of biological activity, many purine derivatives find application in medicine. Theophylline was previously utilized as a diuretic, but it no longer plays a role in this type of therapy. The most important use for theophylline and certain of its salts (e.g., theophylline ethylenediamine [*317-34-0*], theophylline cholinate [*4499-40-5*]), and such derivatives as diprophylline (**13**) [*479-18-5*] [18], proxyphylline (**14**) [*603-00-9*] [19], etofylline (**15**) [*519-37-9*], [18], or bamifylline (**16**) [*2016-63-9*] [20] involves their bronchodilating antiasthmatic properties (→ Antiasthmatic Agents, Chap. 2.2.). More recent pharmaceutical developments have resulted in a trend toward increasing use of theophylline itself rather than its derivatives.

Another theophylline derivative, reproterol (**17**) [*54063-54-6*] [21], in which the xanthine skeleton is combined with a sympathomimetically active structure, shows only sympathomimetic action (→ Antiasthmatic Agents). Pentoxifylline (**18**) [*6493-05-6*], a theobromine derivative, is employed as a vasodilator [22] (→ Cardiovascular Drugs).

18

Fenetylline (**19**) [*3736-08-1*] is used as a CNS stimulant [23, 24]; cafedrine (**20**) [*58166-83-9*] as an analeptic agent [24, 25]. Dimenhydrinate [*523-87-5*], the salt of 8-chlorotheophylline [*85-18-7*] [26] and diphenhydramine [*58-73-1*] [26], is a commonly employed antiemetic (→ Antiemetics).

A number of guanine and adenine derivatives are employed as chemotherapeutic agents in treatment of the herpes virus, including acyclovir [*59277-89-3*] [27] and vidarabin [*24356-66-9*] [28] (→ Chemotherapeutics,

Chap. 4.6.1.). 6-Mercaptopurine [29] and 6-thioguanine [30] are applied in the treatment of leukemia (→ Cancer Chemotherapy, Chap. 2.7.).

Caffeine is the purine derivative produced industrially in the greatest quantity. Caffeine stimulates the central nervous system, causing increases in cardiac activity, metabolism, respiration, and blood pressure. It is frequently utilized in combination with analgesics (e.g., acetylsalicylic acid), thereby enhancing the effect of the analgesic [31].

The cosmetic industry exploits caffeine's ability to increase the flow of blood (e.g., in skin cosmetics). Another industrial use relates to the manufacture of copying papers (diazo paper). More important economically is caffeine's use in the soft drink industry. Cola beverages typically contain the compound at a level of about 100 mg/L (→ Beverages, Nonalcoholic, Chap. 4.1.2.→ Beverages, Nonalcoholic, Chap. 4.2.2.). An extensive discussion and evaluation of caffeine metabolism and of potential health hazards associated with its use in beverages and pharmaceuticals is given in [32].

6. Economic Aspects

The worldwide demand for caffeine is ca. 10 000 t/a. Approximately one-third of the total demand is covered by naturally occurring caffeine, the rest by synthetic material. The major share of synthetic caffeine is produced in Germany, with smaller amounts in the United States, Mexico, and the People's Republic of China.

The second most widely distributed purine derivative, theophylline, is entirely synthetic. By far the major portion of the annual demand (ca. 2500 t) is supplied by Germany. The major suppliers of caffeine and theophylline are Knoll and Boehringer Ingelheim.

Theobromine is used mainly in the production of pentoxifylline. The major demand is met by synthetic material and a small part by extraction of cacoa hulls.

1. Introduction

Pyrazolones (**3**) are defined as ketones of pyrazolines (**2**) which are, in turn, dihydro derivatives of pyrazole (**1**):

1 Pyrazole [*288-13-1*]
2 Pyrazoline [*109-98-8*]
3 5-Pyrazolone [*137-44-0*]

1-Phenyl-3-methyl-5-pyrazolone (**4**) [*89-25-8*] is industrially the most important of the various derivatives, being the basis of many dye precursors and a range of pharmaceuticals:

4

Replacement of the methyl group by a COOH or $COOC_2H_5$ group gives the corresponding 3-carboxy- or 3-carbethoxypyrazolones, which are important dye precursors.

Pyrazolone chemistry began in 1883 when Ludwig Knorr first reacted phenylhydrazine with acetoacetic ester [2]. He thought that he had found a new quinoline derivative, but only later did he realise that his new compound was a pyrazolone (**4**). Since pharmacological tests on this substance showed relatively weak potency, Knorr reacted the pyrazolone with methyl iodide in methanol, at the suggestion of the pharmacologist Wilhelm Filehne [3]. This new pyrazolone, named Antipyrin, was an effective analgesic and antipyretic. Thus Antipyrin formed the basis of a range of pharmaceuticals with similar effects such as Pyramidon, Novalgin, and Butazolidin.

When pyrazolones were discovered as coupling components for azo dyes in the late 1800s [4], they rapidly increased in importance. Pyrazolones are still economically important precursors for dyes and pharmaceuticals today.

2. Properties

Most pyrazolones are colorless to yellow solids with melting points of over 100°C, although some of them can be distilled. They are generally insoluble in nonpolar solvents, but soluble in polar ones. Some pyrazolones, particularly those with lower molecular masses, can be recrystallized from hot water. The UV and IR spectra of pyrazolones are very complex and not very meaningful because of tautomerism. Pyrazolones possess both basic and acidic character. The weakly acidic character generally predominates, so they can be titrated with strong bases. However, some pyrazolones can also be titrated with perchloric acid in glacial acetic acid. Most pyrazolones are readily soluble in aqueous alkali.

1-Phenyl-3-methyl-5-pyrazolone (**4**) can exist in 3 tautomeric forms:

KATRITZKY [5], ELGUERO [6], and DORN [7] have carried out extensive investigations into the tautomerism of various pyrazolones. By means of UV, IR, and NMR spectroscopy and measurement of p*K* values it was shown that for 1,3-disubstituted 5-pyrazolones in aqueous solution 90 % of the NH form is in equilibrium with 10 % of the OH form, while in nonpolar solvents such as carbon tetrachloride or cyclohexane the CH form predominates. The C-unsubstituted 5-pyrazolones exist exclusively in the OH form in dimethyl sulfoxide. Electron donors on C-3 shift the equilibrium towards the CH form.

2.1. Reactions

Because of the keto – enol tautomerism the 4-position in the pyrazolone ring is particularly reactive. It exhibits the behavior typical of an active methylene group and can thus undergo condensation, alkylation, acylation, coupling, and dimerization reactions.

Alkylation. Because of the dependence of the equilibrium on the solvent and pH, 1,3-disubstituted 5-pyrazolones can be alkylated under appropriate reaction conditions at C-4 (CH form), at N-2 (NH form), and at the O atom (OH form). One of the longest known reactions of this type is the alkylation at N-2, first carried out in 1884 by KNORR, who treated **5** with methyl iodide in methanol at 100°C under pressure and obtained 1-phenyl-2,3-dimethyl-5-pyrazolone (**6**) [*60-80-0*] (Antipyrin):

Today this methylation is carried out with methyl chloride or dimethyl sulfate. If dimethyl sulfate in an alkaline medium or methyl iodide and sodium methoxide are used [8], alkylation occurs predominantly at C-4, giving 4,4-dimethylpyrazolones. However, *N*- and *O*-alkylation are observed as side reactions.

Exclusive *O*-alkylation can be achieved by treatment with diazomethane in methanol. In this way PECHMANN [9] succeeded in producing 5-methoxy-3-methyl-1-phenylpyrazole [*27349-35-5*], which rearranges to Antipyrin (**6**) on heating to 250°C [10].

Acylation. Reaction of 1,3-disubstituted 5-pyrazolones with acetic anhydride and sodium acetate [11] or with acetyl chloride and calcium hydroxide in dioxane [12] gives the 4-acetyl compounds.

O-Acetyl compounds are obtained by treatment with acetyl chloride in benzene. If the 1-position is unsubstituted, acetylation takes place predominantly at N-1 [13].

Halogenation occurs almost exclusively at the 4-position. Passing chlorine into an acetic acid solution of a pyrazolone gives the 4,4-dichloropyrazolone. The same product is formed on treatment with phosphorus pentachloride or sodium hypochlorite. 4-Chloropyrazolones can be most easily produced by reduction of 4,4-dichloropyrazolones with hydriodic acid at room temperature.

The corresponding mono- and dibromo compounds are obtained by bromination in glacial acetic acid. The monobromo compound is formed by using an equimolar quantity of bromine. Treatment with phosphorus tribromide gives exclusively 4,4-dibromopyrazolones.

The corresponding iodo compounds can be produced with potassium iodide in aqueous alkaline solution. However, as these compounds are very unstable and light sensitive, they are difficult to obtain pure [14]. When pyrazolones are treated with phosphorus oxychloride under pressure at 150 °C, C=O cleavage occurs to give 5-chloropyrazoles [15].

Nitration. 4-Nitropyrazolones are obtained either by direct nitration under mild conditions or by oxidation of the corresponding nitroso compounds, which are readily accessible by treatment with nitrous acid.

Oxidation. Mild oxidizing agents such as arylhydrazines react with 1-aryl-3-methyl-5-pyrazolones to give 4,4′-bisarylmethylpyrazolones:

7 [*7477-67-0*]

These compounds can also be formed during pyrazolone synthesis if the arylhydrazine is present in excess.

Stronger oxidizing agents such as iron(III) chloride give the indigo dye, Pyrazole Blue (**8**).

8 [*6334-24-3*]

Oxidation in alkaline solution often gives the corresponding 4-hydroxy compounds. Very strong oxidizing agents such as potassium permanganate cleave the pyrazolone ring.

Condensation Reactions. Like all compounds with a reactive methylene group, pyrazolones react at C-4 with aldehydes and ketones. Depending on the reaction conditions both mono- and bispyrazolone derivatives can be formed. Reaction with formaldehyde leads to introduction of a hydroxymethyl group:

[*86467-82-5*]

Coupling Reactions. Besides alkylation, coupling reactions between pyrazolones and aromatic diazonium salts for the production of azo pigments and dyes have achieved the greatest industrial importance:

3. Production

Industrially 1-aryl-3-methyl-5-pyrazolones are produced by condensation of arylhydrazines with acetoacetic esters or acetoacetamide [*5977-14-0*]:

In this process, in which instead of acetoacetamide, diketene in the presence of ammonia can be used [16], the hydrazone formed initially is not isolated. Arylmethylpyrazolones are now generally produced from the corresponding amines, without isolating the intermediates:

1-Aryl-5-Pyrazolone-3-Carboxylic Acids. Besides acetoacetic ester and acetoacetamide, which give methylpyrazolones, diethyl oxalacetate [*63277-17-8*] has become important for the production of 3-carboxy- and 3-carbethoxypyrazolones:
